

use warnings;

near the top of your program. I recommend you switch warnings on, and fix every problem that causes a warning immediately.

- Now, what sort of things give run-time warnings?
- We have mentioned several times that functions return *the undefined value* when they fail; that uninitialized scalar variables (and array and hash elements) have *the undefined value*, etc.
- Perl's *undefined value* (written as undef) is analogous to the concept of a *null pointer*.
- It is *different from* the empty string '' the empty string is a *string of length 0* whereas undef is not a string at all.
- However, undef behaves like the empty string in string contexts, like 0 in numeric contexts, and like false in boolean contexts.

my @pairs = (0,

"zero"

"undef",

"one".

"17.3",

'hello', "hello");

using the function defined, as in:

print "\$label: <\$display>, \$boolstr\n";

introduces a new operator: my \$display = \$testval // "UNDEF";

my \$display = defined \$testval ? \$testval : "UNDEF";

while((\$testval,\$label,@pairs) = @pairs)

undef,

17.3,

foreach (testval, label) in @pairs

1.

"emptystr"

my \$boolstr = \$testval ? "true" : "false";

• The program runs fine without warnings, but with '-w', a use of

• To fix this, decide how to display undef, and test for defined-ness

uninitialized value \$testval in a string warning appears.

• This form of "value or default" is so common. Perl 5.10

print "\$label: <\$testval>, \$boolstr\n";

• In this fourth session, we'll go over some of the more advanced

• If you put the pragmas:

use strict; use warnings;

near the top of your programs then Perl will perform stricter syntax checks for you. This has several effects - for example, all warnings become fatal errors.

- Let's try adding use strict to eg1 and see what error messages perl -cw eg1 generates.
- Oops! We forgot to declare some of our variables: under use strict, Perl insists that you declare all your variables properly (using my).
- Let's spend a moment making **eg1** work in strict mode declare all our variables.
- Note that we've been declaring our variables all along, but actually we didn't need to do so until we encounter strict mode.

```
Duncan White (CSG)
```

e: Fourth Session December 2011

Perl's Predefined Functions

- Perl has hundreds of predefined functions. Let's look at a few of the most useful ones - consult the Llama or Camel book or perldoc perlfunc for more details.
- Carr = split(/regex/, string, n)
 - Splits a string into an array of pieces, splitting the string wherever the regex matches i.e. the regex indicates what *separates* the interesting parts.
 - If no value of n is given, the maximum number of splits are performed. If \$n is given, the string is split into exactly \$n pieces, the last piece contains the rest of the string.
 - If no string is given then \$_ is used by default. A common use of this is to split \$_ into whitespace separated 'words' or 'tokens':
 my @wd = split(/\s+/);
- \$str = join(sep_string, array)
 - This function joins the elements of the array together, using the given string as a separator, i.e. between every pair of elements.
 - For example:
 - print join(',', @wd);

- The 'my' declarations that we've been using declare *lexical* variables which exist only for the duration of a particular lexical scope (for example, in a particular block).
- They are like *local variables* but if you declare them outside of a block, they exist from the point of declaration down to the bottom of the Perl script and are effectively *global variables*.
- Most of the time, we declare and initialize variables at the same time, but you can declare one or many variables without initializing them by:

my \$a; my(\$x, \$y, @z);

- There's another type of global variable, called *package variables*, declared by replacing 'my' with 'our', as in:
 our(\$x, \$y, @z);
- Later on, we'll see a few places where package variables are needed, but for now I recommend that you use 'my' variables everywhere until further notice.

```

```

n December 2011

erl's Predefined Functions

- push(@array, list)
 - This function appends the given list (or single scalar) to the end of an array.
 - Common use: accumulate entries in an array:

push(@done, \$filename);

- \$x = pop(@array)
 - Remove the last element from the array and return it. Common use: (with push) implement a stack:

push(@stack, (3, 2)); \$x = pop(@stack); # gets 2 \$y = pop(@stack); # gets 3

- \$x = shift(@array)
 - This extracts the first element of the array, removing that element from the array, shifting every other element down one space.
- unshift(@array, list)
 - Opposite of shift: The list (or single scalar) is inserted into the array at the front, shifting all existing elements up out of the way.

Perl's Predefined Functions

- @result = sort(list)
 - This function sorts an array such that each element is placed in an ascending order by default into alphabetical order.
 - You can specify a different sort order, such as numeric, using the highly magical :
 - @sorted = sort { \$a <=> \$b } (@array)
 - Consult perldoc -f sort for more information.
- @result = reverse(list)
 - This function reverses an array (such that each element is placed after all its predecessors).
- @result = glob(wildcard)
 - This performs a shell compatible file glob returning a list of files which match the wildcard. For example glob("*.[ch]") matches all '.c' or '.h' files in the current directory.
- \$len = length(string)
 - This trivial function is the equivalent of C's strlen it returns the length of the given string expression.

```
Duncan White (CSG)
```

ion December 2011

```
Perl's Predefined Functions map
```

- Cresult = map { operation } Carray
 - map is very similar to the functional programming (Haskell etc) map function, which applies an operation to every element of an array, building a new array.
 - Just like grep, within the operation the current array element is stored in a localized \$_.
 - The operation is any valid Perl expression so, for example, eg3:

```
my @orig = (1,2,5,8,9,10,5);
my @doubled = map { $_ * 2 } @orig;
print join(',', @doubled)."\n";
```

will double all the original numbers and then print the results in comma-separated format.

• You can also use map destructively - if you modify \$_ the original element is modified (**eg4**):

```
my @array = (1,2,5,8,9,10,5);
map { $_ *= 2 } @array;
```

does the same but modifies @array in place.

- printf("format string", args);
 - \$str = sprintf("format string", args)
 - When you need more formatting than print can do use printf and sprintf. These are closely modelled on the C functions and are much too complex to explain here... For example, **eg2**:

my \$string = 'pi'; my \$pi = 3.1415926536; printf("<%-10s><%12.8f>\n", \$string, \$pi);

would produce output:

- <pi >< 3.14159265>
- See perldoc -f sprintf for more details.
- Cresult = grep { expr } list
 - This function evaluates the expression for each element in the list (with the element itself stored in a localized copy of \$_), and extracts the elements for which the expression is true.
 - It is equivalent to (but more efficient than):

```
@result = ();
foreach $_ (list) { push( @result, $_ ) if expr; }
```

 Common use - pretend we're the Unix grep utility: my @result = grep { /he*llo/ } @array;

```
Duncan White (CSG)
```

I Short Course: Fourth Sessi

December 2011 10 / 23

Perl's Predefined Functions map

• map cont:

- The operation in a functional map always receives a single array element, but it can return a list of scalars rather than a single scalar, in this case all the *little lists* are appended together.
- For example, **eg5**:

```
my @orig = (1,2,5,8,9,10,5);
my @result = map { $_, $_ * 2 } @orig;
```

generates a pair (x, 2x) from each element of the original array, thus setting @result to a flat list twice as long - (1,2,2,4,5,10..).

• This is often used to turn an array into a hash - when you assign a flattened list of (key,value) pairs to a hash, Perl initialises it pairwise. As in **eg6**:

my @orig = (1,2,5,8,9,10,5);
my %double = map { \$_, \$_*2 } @orig;

• The comma can be written as => to look nicer:

my %double = map { \$_ => \$_*2 } @orig;

 One use of this is to turn an array into a set hash: my %set = map { \$__ > 1 } @orig;

12 / 23

- Practically all languages provide *functions*, *subroutines* or procedures. In Perl, they are called subroutines.
- You decide on a coherent block of code with a nameable purpose, for example, sum up an array and return the total, and give it a name like sumarray.
- Decide what *arguments* sumarray takes, and what *results* it returns. The easiest way of showing this is to write down a typical call:

my \$total = sumarray(@arr);

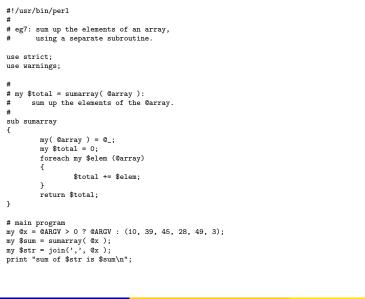

This means: call function sumarray, passing the array @arr in to it, and storing the scalar value that is returned into \$total.

• Then write the outer shell of your function as a sub declaration, including a comment describing the function's purpose:

edefined Functions Defining Our Own Functions

Putting the whole program together:

tions Defining Our Own Functions

- Now, inside the {}, write the body of the function: mv @arrav = @ : my \$total = 0; foreach my \$elem (@array) \$total += \$elem: 3 return \$total:
- Perl flattens all the arguments in a subroutine call into a single list, called @_. Note that the original argument array elements will change if you change Q_ elements.
- Perl's *local variables* are our old friends lexically scoped 'my' variables.
- They spring into existence when we enter the function, eclipsing existing variables of the same names, and disappear when we leave the function.
- In sumarray, we take a copy of Q_ into 'my Qarray' (to avoid any possibility of changing the parameters). Then we declare ourselves two additional 'my' variables \$elem and \$total.
- Finally, to communicate the final result back to the caller we use return \$total. This destroys all the function's local variables.

Prototypes

• Prototypes were added in Perl 5.6 and allow us to specify how many parameters a subroutine takes. In a subroutine header write: sub fred (\$\$@)

• This declares that fred must be called with two scalars and a (possibly empty) array. If Perl has already seen a prototype declaration for sub fred when it parses a call to fred it will produce a warning unless there are at least two scalar arguments.

• One option is to separate the prototypes from the subroutines:

```
# first declare the prototypes:
sub fred ($$@);
sub bob ($);
. . . . . .
# define the subroutines from here on, any order:
sub fred
        my( $a, $b, @rest ) = @_;
        . . . . . .
sub bob
£
        my( $arg ) = @_;
```

Ł

}

3

Duncan White

December 2011 14 / 23

- Prototypes are not perfect, they're likely to undergo more change in Perl 6. They don't affect the fact that all arguments to a function call are still flattened into a single list - so you can't just say sub fred (00%) and pass two whole arrays and a hash to fred... To do this, you have to use Perl references - read on.
- Note that a Perl subroutine can return a scalar, an array or a hash - so for example it's fine to think of a subroutine as returning a *tuple*, as in: my(\$a,\$b) = callme(arguments); return (\$x, \$y);

- Exercise: take any of the programs that you've already done in previous sessions and restructure it into several functions with separate prototypes at the top.
- Exercise: Choose some simple recursive function perhaps fibonacci, factorial or quicksort - code it up in Perl, get it working and thus convince yourself that there's nothing abnormal about recursion in Perl. In particular, convince yourself that each recursive call has its own local argument array, and its own local set of my variables.

```
Duncan White (CSG)
```

December 2011

• You can also make a reference to an array (eg9):

```
mv @a = ( 54, 17, 23 );
print "before: " . join(',', @a) . "\n";
my $ref = \@a;
$$ref[2] = 18; # sets $a[2]
print "after: " . join(',', @a) . "\n";
```

- Note that \$\$ref[2] binds like \${\$ref}[2]. This \$\$ref[\$n] syntax is so unpleasant that Perl gives us a nicer alternative: \$ref->[\$n].
- You can dereference the whole array as @\$ref.
- You can also make an anonymous array ref (eg10):

```
my $ref = [ 54, 17, 23 ];
print "before: access via ref: " . join(',', @$ref) . "\n";
$ref->[2] = 18; # overrides '23' value
print "after: access via ref: " . join(',', @$ref) . "\n";
```

• You can also have references to hashes (eg11):

```
my %hash = ( "duncan" => "d.white", "bilbo" => "b.baggins" );
my f = \ \
$ref->{frodo} = "f.baggins"; # stores a new key, value pair
while( my($key,$value) = each(%$ref) )# now print all pairs out
£
 print "$key => $value\n";
3
```

- In Perl 4, the only data structures that existed were scalars, arrays of scalars and hashes of scalars. No multi-dimensional array facilities (array of array ... of scalars) were provided.
- In Perl 5, Larry Wall decided to graft multi-dimensional structures into the language. Rather than change the whole term syntax, he did it by adding a new type of scalar - a *reference*.
- A reference is very like a pointer in C. To make a reference, use the backslash operator (like C's address-of operator, &):

my \$x = 10;my $ref = \x;$

• \$ref now refers to (or points to) \$x. Dereferencing is done by using \$ref instead of a variable name:

print "before: x is \$x\n"; print "before: ref refers to x - value \$\$ref\n"; \$\$ref++· print "after: x is \$x\n";

• Make this into a program **eg8** and try it out...

December 2011 18 / 23

• We can declare anonymous hash refs (eg12):

```
my $ref = { duncan => "d.white", bilbo => "b.baggins" };
$ref->{frodo} = "f.baggins"; # store a new key, value pair
delete $ref->{duncan};
                              # deletes a k,v pair
while( my($key,$value) = each(%$ref) ) # print out all pairs
 print "$key => $value\n";
```

• We can now create hashes of hashes, arrays of arrays, or any combination. For instance:

```
my @fred = (
   { "one" => "ena", "two" => "duo" },
   { "three" => "drei" },
   { "one" => "une", "two" => "deux" }
):
```

- @fred is an array of references to hashes: \$fred[\$r] is now a reference to one hash. %\$fred[\$r] is one whole hash. and \$fred[\$r]->{\$c} is a single element. This last can, as a special convenience, be written as $fred[r]{sc}$.
- Thus, it looks very like a multi-dimensional array, but it isn't really!

References

- How might we printout such a complex data structure as @fred (an array of references to hashes)? There are two ways:
- Write our own function, carefully tailored to the exact

```
specification we want (eg13):
  foreach my $hashref (@fred)
  {
    my @x = ();
    foreach my $key (sort keys %$hashref)
    {
        my $value = $hashref->{$key};
        push @x, "$key->$value";
        }
        print join( ", ", @x ). "\n";
    }
```

• Or use Perl module Data::Dumper - which is designed to navigate and print reference structures (eg14):

```
use Data::Dumper;
... definition of fred ...
print Dumper \@fred;
```

 How does that work? It's complicated... However, the core of it uses a Perl function ref() which takes a reference and returns a string such as 'HASH' to tell you what the reference is currently referring to. Using that information, a reference navigator can be written pretty easily.

```
Duncan White (CSG)
```

December 2011

Exercises

- In the last session, there was a multi-part exercise that attempted to build word frequency indexes of files. We can do more now:
- Use split to allow the indexing program to split each line into multiple words and index each word.
- Convert the indexer into separate functions, nicely laid out. Add prototypes and use strict.
- Record when each data file was last indexed. Write a reindex program to check the modification time of each indexed document file and reindex modified documents.
- Hint: use Perl's stat function to find a file's modification timestamp (see perldoc -f stat for details).
- Familiarise yourself with complex references use the Data::Dumper module to print them out.
- Modify eg13 replacing the entire inner foreach loop that builds the @x array with a map invocation that begins my @x = map If you're feeling brave, you can remove @x altogether and make the body of the outer foreach a single statement beginning print join(", ", map....

References to Functio

• You can also take a reference to a function (a subroutine) and call it (later) through the reference - just like C's *pointer to function* concept:

```
sub fred ($)
{
...
}
my $funcref = \&fred; # ref to function
...
$funcref->( 10 ); # calls fred with arg 10
```

• Perl also allows us to create anonymous function references on the fly, as in:

```
my $doubleme = sub { return 2 * $_[0]; };
my $x = $doubleme->(10);
print "10 doubled is... wait for it.. $x\n";
```

• Using function references, you can do higher order functions, callbacks, factories etc. Lambda calculus in Perl? If you must! map and grep help too.

```
Duncan White (C
```

Perl Short Course: Fourth

December 2011 22 / 23
