Security and Management Policy Specification

Morris Sloman and Emil Lupu, Imperial College

Abstract

Policies are rules governing the choices in behavior of a system. They are increasingly being used as a means of implementing flexible and adaptive systems for management of Internet services, networks, and security systems. There is also a need for a common specification of security policy for large-scale multi-organizational systems where access control is implemented in a variety of heterogeneous components. In this article we survey both security and management policy specification approaches, concentrating on practical systems in which the policy specification can be directly translated into an implementation.
This article provides a survey of some of the work on policy specification for both security management and policy-driven network management. Rather than covering many papers superficially we have concentrated on a few exemplary approaches in more detail, with emphasis on practical rather than theoretical approaches. In a later section we describe examples of security policy specification. Role-Based Access Control provides the grouping of policies (permissions) related to an organizational position, and the Trust Policy Language indicates the use of credential-based policies. We cover various approaches to management policy specification, namely the Policy Description Language for event-triggered policies from Lucent and the ongoing work in the Internet Engineering Task Force, Distributed Management Task Force (IETF/DMTF) on standardization of policy information models. We describe our Ponder policy specification language that combines many of the above concepts and can be used for both security and management policies. We do not discuss routing policies since these have been described in a recent survey [5]. Web references to much of the work on policy and many of the papers described here can be found in [6].

Security Policy Specification

Role-Based Access Control

Although Role-Based Access Control (RBAC) is not directly concerned with policy specification, it has been accepted as a security model that permits the specification and enforcement of organizational access control policies. The fundamental concept on which RBAC relies is that permissions are associated with roles rather than users, thus separating the assignment of users to roles from the assignment of permissions to roles. Users acquire access rights by virtue of their role memberships, and they can be dynamically assigned or removed from roles without changing the permissions associated with their role. Multiple users can be assigned to the same role, and multiple roles can be assigned to the same user.

Although the concept of role has existed in a fairly similar form for a long time in both systems security and role theory, the work presented by Sandhu in [7] and the first RBAC workshop [8] have prompted a renewed interest in this approach, which is now adopted, to different degrees, in many commercial products.

The main goal of RBAC goes beyond the concept of role and aims to simplify permission management in large organizations. To achieve this, roles must be combined in a structured way and permissions must be reused. The most popular approach relies on role inheritance where senior roles such as team leader or project supervisor inherit the permissions of junior roles such as employee, team member, and so on. However, other approaches such as assigning roles to other roles can also be found in the literature.

A possible role hierarchy for an academic institution is described in Fig. 1, which illustrates how role inheritance provides the sharing of resources through common lower-level roles and the aggregation of permissions through inheritance of permissions to the higher level. However, such role inheritance hierarchies are not without shortcomings since there are numerous exceptions to the rule that senior roles inherit all the permissions of junior roles. Most notably, access to private files and permissions granted by virtue of a competency are not inherited. For example, the head of department does not usually inherit the access rights of a system administrator. To accommodate such situations it is necessary to create private roles, as shown in Fig. 1, which group the permissions not inherited upward in the hierarchy. Implementing an RBAC system with inheritance of permissions between roles considerably reduces the number of permissions in the system. However, in a distributed system it may also render access control checks, performed on each invocation, more complex since the inherited roles may be stored remotely and checking the inherited permissions may require several remote invocations. To avoid this increased complexity, a capability-based system may be more appropriate for RBAC since it shifts the responsibility for collecting the inherited permissions to the user (subject) system, and this is done prior to the access control check.

Several constraints may apply to an RBAC model across its associations, between users and roles, roles and permissions, or between roles themselves (inheritance) [9]. Among these, separation of duty constraints, which identify mutually exclusive sets of permissions a user is not allowed to hold, have been the subject of the most intensive work.

Figure 2 shows an overview of the RBAC model with the various relationships between user roles and permissions, and the constraints. The model presented in [7] also introduces the concept of sessions. A session groups the permissions from a selected number of roles the user may want active at a given moment in time (i.e., in a work session). The user can then use all access rights from the active roles in order to carry out his tasks.

The RBAC model presented above is the foundation from which many variations have developed. In particular, team-based access control has developed as a means of simultane-
Although the concept of a role is not new, the introduction of RBAC models has fostered a change from the traditional mandatory and discretionary access control models to new frameworks where the access control policy is neither rigidly embedded in the implementation nor left to the owner of each resource, but can be implemented on the basis of clearly specified organizational policies.

IBM’s Trust Policy Language

For frameworks that support sophisticated authorization policy specification and implementation using public key certificates as credentials to authenticate identities or membership of groups [10, 11]. This can be particularly useful for e-commerce and Internet applications. We will describe the IBM Trust Policy Language (TPL) and support system as an exemplar of this approach [12].

TPL uses XML to define policy rules that specify the criteria for a client to be assigned to a group which is similar to a role. Standard database or operating system authorization rules are then used to define what resources a group can access, as shown in Fig. 3. Thus, the authority that issues certificates for a role can be completely different from the one that defines access control policy for a resource.

The TPL policy consists of a list of required X509 certificates which permit a client to become a member of a group and a Boolean function relating the values of the fields in one or more certificates to define group membership criteria. Example groups include employees of an organization, registered customers for a merchant, or recognized cardiologists at a hospital. An example medical group membership criteria could be possession of 3 recommendation certificates from hospitals with recommendation level >3.

A certificate identifies the issuer, the subject to whom they are issued (which could be a name or an anonymous public key), and a list of name-value pairs that may contain information such as age, sex, and rank of the holder. The certificate may also contain links to repositories for additional certificates for the issuer or subject since multiple certificates may be needed for a client to be assigned to a group.

The TPL policies shown in Fig. 4 are for a retailer (the self group in the policy) to give discounts to preferred customers who are employees of a department of a partner company. Entities that have partner certificates, signed by the retailer, are placed in the group partners. The group department is defined as any user having a partner certificate signed by the partners group. Finally, the customer group consists of anyone that has an employee certificate signed by a member of the departments group who has a rank > 3.

TPL is available for download from IBM Alphaworks and is very flexible as a means for defining authorization policy for an Internet service, but the XML syntax is rather verbose and unreadable. Although a policy can have multiple rules, there is no inheritance or reuse between different policy specifications, and it is not suitable for specifying security management policy.

Other Security Policy Specification Approaches

There has been considerable interest in logic-based approaches to specifying authorization policy as exemplified by [13, 14]. They assume a strong mathematical background, which can make them difficult to use and understand, and they do not easily map onto implementation mechanisms. The ASL language [13] includes a form of meta-policies called integrity rules to specify application-dependent rules that limit the range of acceptable access control policies. Although it provides support for RBAC, the language does not scale well to large systems because there is no way of grouping rules into structures for reusability. A separate rule must be specified for each action. There is no explicit specification of delegation and no means of specifying authorization rules for groups of objects that are not related by type.

Ortalo [14] describes a language to express security policies in information systems based on the logic of permissions and obligations, a type of modal logic called deontic logic. Standard deontic logic centers on impersonal statements of the form “it is obliged that p” that do not necessarily
identify to whom the obligation applies. Ortalo accepts the axiom \( Pp = \neg O \to p \) ("permitted p is equivalent to not p being not obliged") as a suitable definition of permission. In our view, an obligation policy requires a relevant authorization policy to permit the actions defined in the obligation, but an obligation policy does not imply an authorization policy.

Others focus on the specification and implementation of access control policies for mobile agent systems. In most cases the studies focus on reconfigurable access control policies in the Java environment. They have included both the translation of higher-level policies into Java security policies as well as different access control mechanisms within Java [15, 16].

Management Policy Specification

Lucent’s Policy Definition Language

The Policy Definition Language (PDL) was developed at Lucent Bell Laboratories for network management and is based on active database declarative event-condition-action rules that is, obligation policies [17]. It is a very simple language with two main constructs: a policy rule corresponding to an obligation policy and a rule for triggering other events:

Policy Rule: event causes action \((t_1 = v_1, \ldots, t_k = v_k)\) if condition

Policy Defined Event (pde):

\(\text{event triggers pde } (t_1 = v_1, \ldots, t_k = v_k)\) if condition

where \(t_i\) = parameter (attribute) type and \(v_i\) = value. Every event has a timestamp and the URL of the source that generated it. Primitive events can be generated by the managed environment or by other PDEs. An Epoch is an application-specific time window in which a set of events are considered to occur simultaneously e.g., day, hour, second. Complex events include:

- \(e1 \& e2 \& \ldots \& en\) = conjunction of events in an epoch
- \(e1|e2|\ldots|en\) = disjunction of events in an epoch
- \(!e\) = no occurrence of event in an epoch
- \(^e\) = a sequence of zero or more occurrences of an event
- \((e_1 \& e_2 \& \ldots \& en)\) or group \((e_1|e_2|\ldots|en)=a\) single event grouping all instances of the complex event. If there are \(n\) instances of \(e_1\) and \(m\) instances of \(e_2\) in an epoch, there is only one occurrence of group \((e_1 \& e_2)\) instead of \(m \times n\) occurrences.
- \(\text{count } (e, x, x > 4)\) counts the number of occurrences of event \(e\) for which parameter \(x > 4\) is true.
- Other aggregations (max, min, ave, etc.) relating to event parameters.

An example is given in Fig. 5 of the use of PDL to define a policy for a network component that rejects call requests when in overload mode.

PDL is implemented and used in Lucent switching products [18]. It shows that event-condition-action rules are a very flexible approach to specifying management policy. It has also been extended to specify complex workflow tasks. However, it does not support any form of policy composition or reuse of specifications.

CIM Policy Model

The DMTF [19], in collaboration with the IETF Policy work group [20], are defining a policy information model as an extension to the Common Information Model (CIM), known as PCIM [21]. An information model is "an abstraction and representation of the entities in a managed environment — their properties, operation, and relationships." This is independent of any specific repository, application, protocol, or platform. The IETF is defining a mapping of the PCIM model to a directory schema so that a Lightweight Directory Access Protocol (LDAP) directory can be used as a repository. The CIM defines generic objects such as managed system elements, logical and physical elements, systems, service, and service access point. The Policy Model defines a policy rule and its component policy conditions and policy actions as shown in Figs. 6 and 7. The assumption is that a policy rule is of the form if <condition set> then do <action list>. The condition set can be expressed in either disjunctive or conjunctive normal form. Note that there is no explicit triggering event specified as part of the policy, although it is similar to an obligation policy. It is assumed that the agent interpreting the event will evaluate the policy when an implicit event occurs such as a new session setup or possibly on every message.

Policy rules may be aggregated into nested policy groups to define the policies pertaining to a department, user, and so on. Conditions and actions may be specific to a rule or can optionally be stored separately in a policy repository and reused by multiple rules. Sophisticated time period conditions can be defined in terms of times, masks for days in a week, days at beginning or end of month, months in year, and so on. The actions can be defined as being sequential or any order.

The IETF has also defined extensions to PCIM called the QoS Policy Information Model (QPIM), which contains a set of abstractions specific to integrated services (IntServ) and differentiated services (DiffServ) management [23]. For exam-

| Overload threshold: (time outs/calls made) \(> t\) |
| Normal threshold: (time outs/calls made) \(< n\) |

Events: normal, restricted : pde

callMade, timeOut, powerOn: system events /* the above events have no attributes */

Actions: restrictCalls, acceptAll

Policies: powerOn triggers normal // a normal event is triggered when the component is switched

normal, ^ (callMade | timeOut) triggers restricted
if count (timeOut) > t * count (callMade)
/* after a normal event, a sequence of callMade or timeout events will trigger restrictCalls if the overload threshold is exceeded */

restricted causes restrictCalls // sets overload mode to reject call requests

restricted, ^ (callMade | timeout) triggers normal
if count (timeOut) < n * count (callMade)
/* when in overload mode, a sequence of callMade or timeout events will trigger normal if the normal threshold is exceeded */

normal causes acceptAll

/* Assumes only one callMade or timeOut event per epoch */

Figure 5. A PDL example.
ple, they have abstract objects for classifiers, meters, shapers, droppers, and queues, which can be mapped onto the control elements provided by a specific DiffServ router. Specific priority values are assigned to policy rules to resolve conflicts. A simple DiffServ OPIOM Policy is shown in Fig. 8.

As can be seen from Fig. 8, the LDAP schema representation of a very simple policy is extremely verbose and not really aimed at human interpretation. It is assumed this will be generated from a graphical tool of the form provided by a number of vendors or from a high-level language such as Ponder, described in a later section. PCIM does not distinguish between authorization and obligation policies. The emphasis in the working groups has been on QoS policies that can be considered obligation policies without event triggers. However, they can specify simple admission control policies by means of an action to accept or deny a message to give the effect of a positive or negative authorization policy. The term role is defined as a characteristic of a managed element and is used as a means of identifying elements to which a policy applies; for example, a gigabitEthernet role policy may apply to all elements that have a Gigabit Ethernet interface.

It is assumed that policies are objects stored in an LDAP directory service. A policy consumer (policy decision point, PDP) retrieves policies from the policy repository (e.g., LDAP server). A policy execution point (PEP), such as a router, requests policy decisions using the Common Open Policy Service Protocol (COPS). The PEP enforces the policy, for example, by permitting/forbidding requests or allocating packets from a connection to a particular queue. A PEP and PDP could be combined into a single component. Note that there is no explicit event to trigger an IETF policy. An implicit event such as a packet arrival at a router will trigger the search for applicable policies. The policy condition will typically define a specific address or range of source or destination IP addresses or ports to which a policy applies, so this information taken from the packet can be used to find which policies apply. It is only practical for the PEP to query the PDP for a decision on comparatively infrequent packets such as an IntServ request related to a connection setup. If policy decisions are needed on every packet, such as for DiffServ, these have to be preloaded into the PEP by the PDP using the COPS policy provisioning mode. Note that the use of COPS is not mandated by the IETF, and other protocols such as SNMP or HTTP could be used for transferring policy information. There have been suggestions for extensions to the IETF approach to include explicit events for policies that deal with failures, overload situations, and so on, but so far nothing concrete has emerged.

**Other Approaches to Policy Specification**

There are a number of vendors producing policy-based management tools, usually with a graphical user interface for defining policies and allocating them to devices to which they apply. These generally follow the approach of the IETF policy work, which is still in progress, so there are no standards yet to comply with. Initially the main focus was on QoS management, but some of the vendors are extending this to include support for provisioning of virtual private networks (see [6] for links to vendor Web sites). Reference [24] gives a detailed description of the architectures and algorithms needed to support an IETF approach to policy-based networking. It covers some of the issues of translating from higher-level service level goals into policies for specific components in the network and how to distribute the policies to the relevant components.

The ODP Reference Model Enterprise Viewpoint [25] defines concepts for specifying an abstraction of a system within a defined environment in terms of the system’s purpose, its scope, and the policies that apply to the system from its environment as well as those defined within the system.
The current specification defines terms such as policy, authorization, prohibition, obligation, role, domain, and community, but there is no associated language by which a system can be clearly specified, analyzed, or implemented. There have been several attempts at defining Enterprise Viewpoint specifications by using the Unified Modeling Language (UML), possibly with added extensions [26–28]. Proposals have alternated between modeling policies as notes attached to the design elements, OCL constraints, or additional extensions to UML. [27] indicates that OCL is not directly suitable for expressing ODP prohibitions or obligations. These approaches encounter difficulties related to the level of abstraction of the specification. Enterprise Viewpoint specifications are intended to be more general and more abstract than the system design elements of UML. Hence, Enterprise Viewpoint concepts are not defined in UML but can be realized by a design that could be specified in UML. For example, an authorization policy is implemented by a set of objects such as capabilities, certificates, or access control list entries, and an obligation can be realized by the implementation of a particular activity diagram or collaboration. However, the enterprise-level description requires a more abstract representation of the policy than the diagram of invocations that implement it. It is therefore important to be able to identify a minimal and concrete representation for the Enterprise Viewpoint concepts, which represent functional aspects of the system rather than encumber a design notation with abstract concepts that need to be implemented by other representations in the same

Objectclass: qosPolicyNumberValue
Type: IntegerOID
PortValue: 80
The role type ServiceEngineer models a service engineer role in a mobile telecommunications service. A service engineer is responsible for responding to customer complaints and service requests. The role type is parameterized with the calls database, a database of subscribers in the system and their calls. The obligation policy serviceComplaint is triggered by a customerComplaint event with the mobile number of the customer given as an event attribute. On this event, the subject of the role must execute a sequence of actions on the calls-database in order to check the information of the subscriber whose mobile number was passed in through the complaint event, check the phone list and then trace the signal reception. Note that the obligation policy does not specify a subject as all policies within the role have the same implicit subject.

Domains

Domains provide a means of grouping objects to which policies apply and can be used to partition the objects in a large system according to geographical boundaries, object type, responsibility, and authority, or for the convenience of human managers. Membership of a domain is explicit and not defined in terms of a predicate on object attributes. A domain does not encapsulate the objects it contains but merely holds references to objects. A domain is thus very similar in concept to a file system directory but may hold references to any type of objects, including a person. A domain that is a member of another domain is called a subdomain of the parent domain. A subdomain is not a subset of the parent domain, in that an object included in a subdomain is not a direct member of the parent domain but an indirect member; that is, a file in a subdirectory is not a direct member of a parent directory. An object or subdomain may be a member of multiple parent domains (i.e., domains can overlap). An advantage of specifying policy scope in terms of domains is that objects can be added and removed from the domains to which policies apply without having to change the policies. Domains have been implemented as directories in an extended LDAP service.
Ponder Primitive Policies

Authorization policies define which activities a member of the subject domain can perform on the set of objects in the target domain. These are essentially access control policies to protect resources and services from unauthorized access. A positive authorization policy defines the actions subjects are permitted to perform on target objects. A negative authorization policy specifies the actions subjects are forbidden to perform on target objects.

The language provides reuse by supporting the definition of policy types to which any policy element can be passed as a formal parameter. Multiple instances can then be created and tailored for the specific environment by passing actual parameters, as shown in Fig. 9.

Policies can also be declared directly without using a type, as shown in the negative authorization policy in Fig. 10, which also shows the use of a time-based constraint to limit the applicability of the policy.

Ponder also supports a number of other basic policies for specifying security policy. An information filtering policy can be used to transform input or output parameters in an interaction. For example, a location service might permit access to detailed location information, such as the specific room in which a person is, only to users within the department. External users can only determine whether a person is at work or not. Delegation policy permits subjects to grant privileges they possess (due to an existing authorization policy) to grantees to perform an action on their behalf (e.g., passing read rights to a printer spooler in order to print a file). Refrain policies define the actions subjects must refrain from performing (must not perform) on target objects even though they may actually be permitted to perform the action. Refrain policies act as restraints on the actions subjects perform and are implemented by subjects. See [30] for more details and examples of these policies.

Obligation policies are event-triggered condition-action rules similar to Lucent's PDL, and define the activities subjects (human or automated manager components) must perform on objects in the target domain. Events can be simple (i.e., an internal timer event) or external events notified by monitoring service components (e.g., a temperature exceeding a threshold or a component failing). Composite events can be specified using event composition operators (Fig. 11).

Ponder Composite Policies

Ponder composite policies facilitate policy management in large complex enterprises. They provide the ability to group policies and structure them to reflect organizational structure, preserve the natural way system administrators operate, or simply provide reusability of common definitions. This simplifies the task of policy administrators.

Roles provide a semantic grouping of policies with a common subject, generally pertaining to a position within an organization such as department manager, project manager, analyst, or ward nurse. Specifying organizational policies for human managers in terms of manager positions rather than persons permits the assignment of a new person to the manager position without respectifying the policies referring to the duties and authorizations of that position. A role can also specify the policies that apply to an automated component acting as a subject in the system. Organizational positions can be represented as domains, and we consider a role to be the set of authorization, obligation, refrain, and delegation policies with the subject domain of the role as their subject. A role is just a group of policies in which all the policies have the same subject, which is defined implicitly, as shown in Fig. 12.

Managers acting in organizational positions (roles) interact with each other. A relationship groups the policies defining the rights and duties of roles toward each other. It can also include policies related to resources that are shared by the roles within the relationship. It thus provides an abstraction for defining policies that are not the roles themselves but are part of the interaction between the roles. The syntax of a relationship is very similar to that of a role, but a relationship can include definitions of the roles participating in the relationship. However, roles cannot have nested role definitions. Participating roles can also be defined as parameters within a relationship type definition as shown in Fig. 13.

Many large organizations are structured into units such as branch offices, departments, and hospital wards, which have similar configurations of roles and policies. Ponder supports the notion of management structures to define a configuration in terms of instances of roles, relationships, and nested management structures relating to organizational units. For example, a management structure type would be used to define a branch in a bank or a department in a university and then instantiated for particular branches or departments. A management structure is thus a composite policy containing the definition of roles, relationships, and other nested management structures, as well as instances of these composite policies.

Figure 14 shows a simple management structure for a software development company consisting of a project manager, software developers and a project contact secretary. Figure 15 gives the definition of the structure.

Ponder allows specialization of policy types through inheritance. When a type extends another, it inherits all of its elements, adds new elements, and overrides elements with the same name. This is particularly useful for specialization of composite policies. For example, it would be possible to
define a new type of mobile systems project manager from a project manager role (Fig. 12) with additional policies.

In Ponder a person can be assigned to multiple roles, but rights from one role cannot be used to perform actions relating to another role. A person can also have policies that pertain to him/her as an individual and have nothing to do with any roles. In RBAC inheritance is based on policy instances, and all policies are defined in terms of roles. This means RBAC requires a much more complicated role structure to separate the policies that are inherited from those that are private.

A compiler has been implemented for the Ponder language. Various back-ends have also been implemented to generate firewall rules, Windows access control templates, Java security policies [15], and Java obligation policy rules for interpretation by a policy agent. We also have a system to automatically disseminate policies to the relevant agents that will interpret them; that is, to subjects for obligation and refrain policies, and access control agents for authorization and filter policies [32].

Research Issues

Conflict Analysis

There are a number of different conflicts that can arise from policies. For example, it might be possible that different OPMI policies apply for marking packets relating to a specific flow as one selects packets based on a range of IP addresses, and another selects packets based on port numbers. The solution proposed in the IETF framework advocates assigning explicit priorities to policies, but this is notoriously difficult to do in large systems where many different people are responsible for specifying policies. In Ponder modality conflicts arise between positive and negative policies that apply to the same subjects, targets, and actions [33]. These can be detected by syntactic analysis of the policies as the conflict can be determined by detecting overlap of subjects, targets, and actions. However, the analysis detects only potential conflicts rather than actual conflicts since constraints may limit the applicability of the policy to disjoint sets of circumstances (e.g., different times of day). While modality conflicts can be detected syntactically, other conflicts can only be determined by understanding the actions being performed by the policies. For example, there will be a conflict between two policies that result in the same packet being placed on two different queues. Similarly, separation of duty conflicts arise from authorization policies that permit the same person to approve payments and sign checks. Generally, these conflicts are application-specific, and to detect them it is necessary to specify the conditions that result in conflict. The approach is therefore to specify constraints on the set of policies (i.e., meta-policies) using a suitable notation and then analyze the policy set against these constraints to determine if there are any conflicts [33]. Whether conflicts occur or not may depend on runtime parameters specified in constraints such as time or the current state of the components to which the policy applies. It is thus rather difficult to determine all possible conflicting conditions in advance, so it is still necessary to detect conflicts at runtime. Furthermore, when conflicting policies are detected it is not obvious how to resolve the conflicts automatically. Explicit priority may work in some cases. In some situations, negative authorization policies should override positive ones, but in other situations the positive authorization is an exception to a more general negative authorization. In some situations more specific policies that apply to a department may override general policies applying to the whole organization.

Although some progress has been made in dealing with policy conflicts [24, 33], significant challenges remain to be addressed. In particular, how can one detect conflicts when arbitrary conditions restrict the applicability of the policies? Sometimes, it is possible to compare restrictions placed by the constraints. For example, it is possible to detect if two time intervals overlap or if the policies apply when subjects are in different states (e.g., active or standby). However, the problem remains unsolved in the general case. Other challenges concern the different levels of abstraction at which policy is specified. Conflicts between organizational goals will inevitably lead to conflicts between the policies derived from these goals. Some policies will trigger complex management procedures which require the execution of actions that may be specified as part of different policies. This renders the task of ensuring the consistency of a policy specification much more complex.

Refinement

Both network and security policies are specified with a view to fulfill organizational goals and service level objectives. The process of deriving a more concrete specification from a higher-level objective is termed refinement. Although the goal of automating refinement of management and security policies from higher-level objectives remains worthy, it is not practical for all but the most trivial scenarios. However, this does not preclude the partial automation of this process or providing tools that can assist human managers to refine high-level abstract policies into more concrete ones. This will require representing and taking into account domain-specific knowledge as well as more general techniques and methodologies. Currently the most promising approach seems to be investigated in requirements engineering, and relies on identifying, recognizing, and instantiating refinement patterns [34]. A much simpler approach of integrating service level goals with policies is described in [35].

It is desirable to maintain the properties of consistency and completeness when refining an abstract goal into a set of more concrete policies. By consistency we mean that there is no conflict between those policies derived by refinement from a high-level goal nor are they in conflict with the other policies within the system. By completeness we mean that the set of policies derived by refinement fully implements the intended specification of the abstract goal. Using established patterns would help toward maintaining both these properties since patterns can be previously checked for completeness and conflicts. Note that this does not ensure that conflicts will not occur with other policies in the system; thus, even when instantiating established patterns it is necessary to perform conflict analysis.
Multiple Levels of Policy

Policies can be used to support adaptability at multiple levels in a network:
- Within network-aware applications
- Within application-aware networks
- At the hardware level to support adaptability in the packet forwarding “fastpath” of network elements

Research is needed on defining interfaces for the exchange of policies between these levels. For example, an application-specific policy may be more efficiently interpreted within a network component, or an application may need to adapt its behavior as a result of adaptation within the network. However, it is not easy to map the semantics of the policies between the different levels. The application may not be aware of what components exist within the network, so how can it specify policies to be interpreted by them?

An interesting variation of the above is to consider a policy feedback loop where the system is monitored to see whether it is performing according to high-level policies or to determine changes in the systems due to faults, new applications, or users appearing, and hence dynamically modify the lower-level policies in order to adapt the behavior.

Conclusions

Management and security are closely linked. Access control is essential to protect objects so that only authorized managers can perform management operations on them. Security needs to be managed to disseminate relevant policies to the agents that will implement them, specific actions are needed to deal with security violations, and flexible policies are needed for response to intrusions. Concepts such as roles are useful for both security and management for grouping the policies applying to a position in an organization.

In this article we have described approaches to specifying both security and management policy and then discussed the Ponder framework which caters for both types of policy.

There is considerable interest in policy-based systems from standardization groups, industry, and academia. However, most of the literature relates to proposed systems or small academic prototypes. There is no reported experience of deploying policy-based adaptive systems in any large-scale system. It is thus too early to judge whether the promised flexibility of policy-based adaptive systems will actually materialize.
