Abstract

It is increasingly important to analyze system security quantitatively using concepts such as trust, reputation, cost, and risk. This requires a thorough understanding of how such concepts should interact so that we can validate the assessment of threats, the choice of adopted risk management, etc. To this end, we propose a declarative language Peal+ in which the interaction of such concepts can be rigorously described and analyzed. Peal+ has been implemented in PEALT using the SMT solver Z3 as analysis back-end. PEALT’s code generators target complex back-ends and evolve with optimizations or new back-ends. Thus we can neither trust the tool chain nor feasibly prove correctness of all involved artefacts. We eliminate the need to trust that tool chain by independently certifying scenarios found by back-ends in a manner agnostic of code generation and choice of back-end. This scenario validation is compositional, courtesy of Kleene’s 3-valued logic and potential refinement of scenarios. We prove the correctness of this validation, discuss how PEALT presents scenarios to further users’ understanding, and demonstrate the utility of this approach by showing how it can express attack-countermeasure trees so that the interaction of attack success probability, attack cost, and attack impact can be analyzed.

1 Introduction

It is well recognized that the analysis of threats to system security goes beyond the exposure and fix of vulnerabilities and that it also has to take account of contextual influences such as risks, trust assumptions, the reputation of domains, etc. However, it is often not clear how such different concepts interact in the threat space (which the attacker controls) or how they should interact in a system design space (which the designer thinks he controls). For example, when the Heartbleed vulnerability became known even security experts could not uniformly agree on whether users should immediately change their passwords on web accounts that used versions of OpenSSL vulnerable to this attack [19]: e.g., it was difficult to know whether the account was compromised, and renewing a password in a compromised account might leak that password to an attacker.

In general, threat analysts have a host of techniques and models at their disposal that allow them to assess security threats, let us mention here attack trees [18, 13, 12] and Stackelberg games for security (see e.g. [10]) as two prominent examples. Also, probabilistic risk analysis [2] offers a rich set of tools that threat analysts may use to study the interaction of factors that influence security. Alas, tools from risk analysis view attackers as passive environments (e.g. a random process modeling life expectancy of a light bulb) and not as active agents (e.g. a cyber

\[^1\] Please cite this research note as Michael Huth and Jim Kuo. Quantitative threat analysis via a logical service: usability, service certification, and case study. Technical Report 2014/10, Department of Computing, Imperial College London, ISSN 1469-4174, 2014.
terrorist who seeks access to programmable logic controllers in a SCADA system). We therefore would like support for modeling the interaction of concepts such as protection cost, impact of successful attacks, perception of risk, reputation of agents, etc., in a system exposed to active attacks. The active nature of attackers suggests to model action and reaction with AND/OR structures, e.g. as present in two-person games or first-order logic. The desire to study interaction of quantitative concepts suggests use of an expressive logical language with appropriate theories for reals; expressiveness means we can easily extend studies to new concepts or interaction modes, and theories enable us to do correct quantitative reasoning. We cannot assume, though, that threat analysts are trained logicians, so we require automated reasoning support for such logics to build auto-interactive verifiers. SMT solvers, e.g. Z3 [14], thus look like apt vehicles for expressing and analyzing such interaction in this manner.

Choosing an SMT solver as back-end also poses problems. Its input language is too complex and universal, since security analysts prefer languages specific to their modeling domain. For code generators from domain-specific languages into SMT back-ends we need assurance that results computed by back-ends are correct and sensible in the modeled domain. Security analysts want results communicated in forms appreciable to them. Finally, users may formulate conditions that are vacuously true, or vacuously false in the modeled domain. This may identify a specification error or it may instead validate that an analyst has realized an important invariant – e.g. that the risk is always below an acceptable threshold. Our paper presents results that directly address this set of problems.

Figure 1 shows how our contributions presented in this paper are realized in the tool PEALT. Users specify Peal+ conditions to be analyzed, and domain-specific knowledge or assumptions; PEALT converts these specifications into Z3 code which the SMT solver Z3 solves; the raw output of Z3 results is then post-processed and analyzed over the Peal+ conditions; and feedback is reported so that all scenarios are certified. The user may then inspect that feedback and either be satisfied or edit conditions or domain specifics for further analysis.

Outline of paper. In Section 2, we present language Peal+ in which threats can be modeled and analyzed when quantitative information contains non-deterministic uncertainty; and we discuss automated vacuity checking. In Section 3, we present an algorithm which independently certifies that scenarios computed from analyses by back-ends such as Z3 are correct for the modeled problem – eliminating the need to trust our code generation methods or back-ends. In Section 4, we discuss how the implementation of Peal+, its analyses, and certification are supported by the use of partial evaluation to render certified scenarios to users in compact ways that should facilitate users’ comprehension. In Section 5, we show Peal+’s utility as intermediate language for
In a given environment, the meaning of scores without intervals \([l, u]\) is that of normal arithmetic over real scores. Set \(s = \{E_e(s_i) \mid 1 \leq i \leq n, e(q_i) = \text{true}\}\)

Figure 2: Semantics \(E_e(\text{pSet})\) of policy sets (acyclic as in Def. 1), given an environment \(e\) that maps predicates to truth values, scores to reals, and resolves non-deterministic choice of uncertainty intervals. Scores \(r\) range over raw scores, \(a\) over constants, \(x\) over variables, and \(p . \text{sc}\) over policy scores. Set \(Z\) equals \(\{E_e(s_i) \mid 1 \leq i \leq n, e(q_i) = \text{true}\}\)

Figure 3 shows a formal grammar for our language Peal+ that can express interaction of security aspects as well as the logical/quantitative analysis of such interaction. Peal+ shares the coarse structure of its predecessor Peal [4, 7]: rules condition a score on a predicate, policies are built from rules, policy sets are built out of policies, conditions are formed out of policy set comparisons; and analyses have conditions as arguments. The meaning of analysis types is the intuitive one of their names seen in Figure 3. The meaning of conditions is given by that of propositional logic and of comparison operators over reals. Thus it suffices to define how policy sets evaluate to reals in an environment in which all predicates have truth values, all real variables have a real value, and all non-deterministic uncertainties are resolved – so all scores evaluate to a real number.

We state this semantics informally here, and formally in Figure 2. A rule \textit{rule} returns its declared score when its declared predicate is true; otherwise, it has no effect. The meaning of a policy is then given as follows: if none of its rules has a true predicate, its meaning is that of its default score; otherwise, its meaning is obtained by first computing the meaning of all scores from its rules with true predicates, and then applying operator \textit{op} to that set of computed reals.

The grammar for scores allows us to write expressions such as 0.45, \(-124.5\), \(0.67 * x\), \(0.5 * p . \text{sc}\), \(0.4 * x \in (-0.1, 0.1)\), or \(0.5 * p . \text{sc} \in [-0.05, 0.05]\) where \(x\) is a real-valued identifier and \(p\) is a policy. In a given environment, the meaning of scores without intervals \([l, u]\) is that of normal arithmetic with variable values given by the environment. The meaning of expressions \(s \in [l, u]\) is \(x + y\) where
Figure 3: Syntax of Peal+ where \( q \) ranges over some language of predicates, constants and variables occurring in \( score \) expressions range over real numbers, and \([realConst, realConst]\) ranges over closed real intervals. For sake of clarity, keywords of Peal+ are written in boldface here, e.g., \( pSet.stat \) denotes the score of \( pSet \).

\[
\begin{align*}
\text{cond} & ::= \quad q \mid \neg \text{cond} \mid \text{cond} \mid \text{cond} \mid \text{cond} \mid \text{cond} \mid \text{cond} \mid \text{cond} \\
op & ::= \quad \text{min} \mid \text{max} \mid + \mid *
pSet & ::= \quad \text{pol} \mid \text{op} (pSet, pSet) \\
pol & ::= \quad \text{op}(\text{rule}) \text{ default } \text{score} \\
\text{rule} & ::= \quad (q \text{ score}) \\
\text{score} & ::= \quad \text{rawScore} \mid \text{rawScore} [\text{realConst}, \text{realConst}] \\
\text{rawScore} & ::= \quad \text{realConst} \mid \text{realVar} \mid \text{realConst} \ast \text{realVar} \\
\text{realVar} & ::= \quad \text{identifier} \mid \text{pSet.stat}
\end{align*}
\]

\( x \) is the meaning of \( s \) in the environment, and \( y \) from \([l, u]\) is the non-deterministic choice of the environment from interval \([l, u]\). To ensure consistency, we require \( l \leq 0.0 \leq u \). For example, \( u < l \) would be logically inconsistent and \( l > 0 \) would suggest to change \( s [l, u] \) to the equivalent but more comprehensible \((s + l) [0.0, u - l]\) when \( l \leq u \). The meaning of variable \( pSet.stat \) is that of \( pSet \) computed by the operational semantics just described. For this to be well-defined, the set of declared policy sets must not create cyclic dependencies in Peal+:

**Definition 1** Let \( p_1 \) and \( p_2 \) be in a set \( P \) of Peal+ policy sets. Then \( p_1 \) depends on \( p_2 \) (written \( p_2 \prec p_1 \)) if there is a score \( s \) in \( p_1 \) that contains or equals variable \( p_2.stat \). Set \( P \) is acyclic if the transitive closure of \( \prec \) over \( P \times P \) is acyclic.

Peal+ extends Peal is important ways: scores may have variables and non-deterministic uncertainty, policy sets have the same composition operators as policies, conditions subsume propositional logic and may compare policy sets, and the result of a policy set can be referred to as variable within a score expression. With these extensions, Peal+ is expressive enough to capture metrics, tree-like models, cost functions, and basic probabilistic computations.

Let us illustrate the use of Peal+ with an example modeling risks that a car rental company may face when renting out cars to clients. Figure 4 shows how rules, policies, policy sets, and conditions for this example are declared in the input language of our tool PEALT. Declarations are divided into blocks by keywords such as POLICIES and lines that begin with \% are used for comments.

A notable feature of the tool input language is the declaration block DOMAIN_SPECIFICS in which specifiers can enter code from the input language of the SMT solver Z3 [14] to further constrain the model. This would typically be used to express assumptions or knowledge of the
modeled domain, and uses Z3 syntax since Z3 is the current back-end of our tool. For example, the model in Figure 4 uses this to express that luxury cars must not be rented out for off-road driving. It represents risk and trust as values in $[0, 1]$, and uses $f(x) = 1 - x$ to convert one into the other. More sophisticated relationships between trust and risk may be captured in Peal+ as well. This Peal+ model is conceptually similar to the use of score cards that assess risks in mortgage applications [16]. Next, we discuss vacuity checking and how our analyses support this.

**Vacuity checking.** The analyses `always_true?` and `always_false?` reduce to satisfiability checks but their intent is to check for so called vacuities [11]: a condition that is always true or always false may be a specification error (as in temporal logic verification of hardware [11]), evidence for a desired invariant or may desire further scrutiny of the specifier. Our tool automatically enforces both types of vacuity check on all declared conditions. The reason is that declared conditions are likely to contribute to input of a declared analysis, and so we want to alert users to those conditions that are vacuously true, or vacuously false.

For example, condition `c1` of the Car Rental Risks example in Figure 4 is reported to be always true, so the “insurance risk” which multiplies monetary loss with its associates risk is never above 50,000. If Z3 can’t decide a vacuity check (output `UNKNOWN`), PEALT reports checked conditions as “may be” vacuities. PEALT only reports names of vacuously true or false conditions. Users who want more detailed feedback as described below need to “promote” such a vacuity analysis into the ANALYSES section, where more detailed feedback is provided. Users may turn automated vacuity checking on or off under “Settings”. We recommend vacuity checks to be done at least once for model validation.

### 3 Scenario certification

Users from high assurance domains need compelling evidence that scenarios computed by back-ends from code PEALT generates are valid for analyzed Peal+ conditions, and they want to be able to relate scenarios to conditions in a comprehensible manner. We report additional support for the latter below. As for the former, what if our Z3 code generation method contains logical mistakes? What if we make wrong assumptions about the operation of the tool Z3? What if some Z3 features we use contain implementation flaws? What if (perish the thought) the inference techniques used in Z3 were to contain mistakes? We think these questions make a compelling case for independently certifying the validity of a scenario discovered for a Peal+ condition. Back-ends such as Z3 compute scenarios that are very compact in that they don’t define values for some variables. Certification therefore needs to be able to reason that these are indeed “don’t care” variables, making certification non-trivial.

Such a certification should be comprehensible to non-experts and efficient – giving it the flavor of an NP problem although the underlying decision problems may be undecidable. Our compositional certification of don’t care variables may lose precision and so may have an inconclusive output. In the latter case, one of the predicates of the scenario may not have a specified truth value. We then set that value to `false` and repeat the certification algorithm on this refined scenario. This process is efficient as it examines conditions compositionally and greedily refines scenarios until it succeeds or not. Refined predicates are set to `false` and `not` to `true`: users want to see as few trees in the forest as possible, and false predicates only have an effect in a policy when all its predicates are false.

This certification process represents a scenario, a model returned by Z3, as a function $I$ that
POLICIES

% policy capturing risk of financial loss dependent on type of rented car
b1 = max ((isLuxuryCar 150000) (isSedan 60000) (isCompact 30000)) default 50000

% policy capturing trust in rentee dependent on type of his or her driving license
b2 = min ((hasUSLicense 0.9) (hasUKLicense 0.6) (hasEULicense 0.7)
         (hasOtherLicense 0.4 [-0.1,0.1])) default 0

% policy that captures potential risk dependent on type of intended car usage
% this policy happens not to be used in the conditions below
b3 = max ((someOffRoadDriving 0.8) (onlyCityUsage 0.4) (onlyLongDistanceUsage 0.2)
         (mixedUsage 0.25)) default 0.3

% policy that accumulates some signals that may serve as additional trust indicators
b4 = + ((accidentFreeForYears 0.05*x) (speaksEnglish 0.05) (travelsAlone -0.2)
         (femaleDriver 0.1)) default 0

% convert trust b2 into risk b2 using f(x) = 1-x
b2_risk = +((True 1.0) (True -1*b2_score)) default 0.0

POLICY SETS

% casting b2_risk into policy set
pSet0 = b2_risk

% policy set that multiplies risk with potential financial loss
pSet1 = *(b1,pSet0)

% casting policy p4 into a policy set
pSet_b4 = b4

CONDITIONS

% condition that the risk aware potential financial loss is below a certain bound
c1 = pSet1 <= 50000

% condition that the accumulated trust is above a certain threshold
b2 = 0.4 < pSet_b4

% condition that insists that two previous conditions have to hold
b3 = c1 && c2

DOMAIN SPECIFICS

% real x models accident-free years of driving, 'truncated' at value 10
(assert (and (<= 0 x) (<= x 10)))

% capturing a company policy: luxury cars must not be used for off road driving
(assert (or (not isLuxuryCar) (not someOffRoadDriving)))

% capturing that the different types of rental cars are mutually exclusive
(assert (and (implies isLuxuryCar (and (not isSedan) (not isCompact)))
         (implies isSedan (and (not isLuxuryCar) (not isCompact)))
         (implies isCompact (and (not isSedan) (not isLuxuryCar)))))

% capturing that cars that are only used in cities are not used in a mixed sense
(assert (implies onlyCityUsage (not mixedUsage)))

% capturing that cars used only for longdistance driving are not used in a mixed sense
(assert (implies onlyLongDistanceUsage (not mixedUsage)))

% capturing domain constraints (or company policy?) that city driving cannot happen off road
(assert (implies onlyCityUsage (not someOffRoadDriving)))

% capturing that cars used only for longdistance driving must drive off road
(assert (implies onlyLongDistanceUsage (not someOffRoadDriving)))

ANALYSES

% is condition c1 always true? this would suggest an invariant
name1 = always_true? c1

% is condition c3 always true? this would suggest a specification error
name2 = always_true? c3

Figure 4: Peal+ model of Car Rental Risks
maps real variables to real numbers or \( \perp \), and predicates to \textit{true}, \textit{false} or \( \perp \). Symbol \( \perp \) models that the scenario did not specify a value for the variable in question. For predicates, \( \perp \) ("unknown") is also the third truth value of Kleene’s 3-valued logic [9]. Figure 8 shows how \textsc{PEALT} reports a scenario for analysis \textit{name2} from Figure 4. To explain our certification, we need to define the refinement of environments, which are all well typed in that they map any variable either to value \( \perp \) or a value of its declared data type – Real or Boolean.

**Definition 2** Let \( \text{env}_1, \text{env}_2 \) be environments over the same set of variables \( \mathbb{V} \). Then \( \text{env}_2 \) refines \( \text{env}_1 \) if for all \( x \in \mathbb{V} \), \( \text{env}_1(x) \neq \perp \) implies \( \text{env}_1(x) = \text{env}_2(x) \).

This means that refinements can change \( \perp \) values of variables to any value of their declared data type, but they cannot change non-\( \perp \) values.

Function \textit{recursivelyCertify}(\( c, I, v, \emptyset \)), seen in Figure 5, checks whether condition \( c \) has truth value \( v \) in the scenario/Z3 model \( I \). It outputs \textit{true} if this claim could be certified, \textit{false} if a logical flaw in the claim was detected, and outputs \( \perp \) otherwise. Wrapper function \textit{certifyWrapper}(\( c, I, v \)) in Figure 5 converts \textit{true}, \textit{false} and \( \perp \) into certification \textit{success}, \textit{failure}, and \textit{inconclusive}, respectively.

The truth value \( v \) used in \textit{recursivelyCertify}(\( c, I, v, \emptyset \)) is determined by the type of analysis. For example, if \textit{always_false}? \( c \) returns \textit{SAT}, it means the found scenario should be evidence for \( c \) being true, and so \( v \) equals \textit{true}. The treatment of analyses with two arguments is similar. For example, for a \textit{SAT} outcome of \textit{implies}? \( c_1 \ c_2 \), the scenario should be evidence for \( c_1 \) being true and \( c_2 \) being false. So we need to achieve two certifications, \textit{recursivelyCertify}(\( c_1, I, \text{true}, \emptyset \)) and \textit{recursivelyCertify}(\( c_2, I, \text{false}, \emptyset \)) for this.

Function \textit{recursivelyCertify} refines \( I \) into an environment \( \text{env}' \) by setting predicates to \textit{false} or adding a statically inferred score to a policy. The latter means that environments are not only defined on predicates and real variables but may also map policy names to their inferred scores. At program point \( l_2 \), such static inference of policy scores is delegated to function \textit{collectCertifiablePolicyScores} in Figure 6. In this extended environment \( \text{env}' \), function \textit{certCond}, shown in Figure 7, determines the truth value of the condition in that environment under Kleene’s 3-valued logic [9]. If that value is \( \perp \), we call \textit{recursivelyCertify} again but with a refined environment that either inferred at least one new policy score or set a predicate to false. If the truth value of the condition is \( \neq \perp \), function \textit{recursivelyCertify} outputs that value.

The need for parameter \( \text{cp} \) and for checking its “progress” comes from construct \textit{pol.sc}, where static inference of a policy score may then enable more such inferences for other policies. Function \textit{collectCertifiablePolicyScores}(\( \text{env} \)) initializes in \( \text{cp} \) an empty hash map. For each declared policy \( \textit{pol} \) it stores in \( \textit{score} \) the output of function \textit{certPolicy}(\( \text{pol, env} \)) depicted in Figure 6. Thus we statically infer the score of \( \textit{pol} \) (rather than consulting \( \textit{env}(\text{p.score}) \) if that were \( \neq \perp \)), so that policy scores are certified before their use in certification of policy scores they depend on. Then either an equality check of \textit{certPolicy}(\( \textit{pol, env} \)) and \( \textit{env}(\text{p.score}) \) is performed – whose failure will fail certification – or we check whether the static analysis returns a real value (i.e. not \( \perp \)), in which case we extend the hash map so that \( \textit{pol} \) has key \( \textit{score} \). Finally, the hash map is returned.

Function \textit{certPolicy}(\( \text{pol, env} \)) first checks whether some predicate \( q \) within policy \( \textit{pol} \) has unspecified truth value in environment \( \textit{env} \). If so, it returns \( \perp \) since the score of \( \textit{pol} \) cannot be determined. Otherwise, if all predicates in \( \textit{pol} \) are false in environment \( \textit{env} \), the default case applies and the evaluation of the default score \( s \) in environment \( \textit{env} \) is returned. Finally, if some predicates in \( \textit{pol} \) are true (and none are then false), we return the application of \( \textit{op} \) to the evaluation \textit{eval}(\( s_i, \text{env} \)) of all “true” score expressions \( s_i \) in environment \( \textit{env} \).
\begin{verbatim}
certifyWrapper(c, I, v) { % condition c, scenario I, and v in \{false, true\}
    if (recursivelyCerti fy(c, I, v, \emptyset) == true) { return success; }
    if (recursivelyCerti fy(c, I, v, \emptyset) == false) { return failure; }
    elseif { return inconclusive; }
}

recursivelyCerti fy(c, env, v, cp) { % returns true, false or ⊥
    cp' = collectCerti fiablePolicyScores(env);
    env' = env + cp'; % program point l2

\}

Figure 7: Function certCond(c, env, v) decides whether condition c has truth value v in environment env, and certPSet(pSet, env) covers this for policies and their composition

Function eval(s, env) has two types of input for s depending on whether s is a raw score \( t_1 \) or contains an uncertainty interval \( [l, u] \) that we translate into Z3 code as a real variable \( t_2 \). This function does a static analysis that consults env(p) when evaluating variables of form \( p.s.c \) and consults env(x) for all other variables \( x \). This consults env(p) and not env(p.s.c) so that policy scores get certified based on certified scores of policies that they depend upon. Although \perp is strict for +, we relax its strictness for * in expressions \( a * x \) when a evaluates to 0.0, in which case \( a * x \) also evaluates to 0.0.

Last, but not least, we turn to function certCond(c, env, v) in Figure 7. It compositionally evaluates over the structure of c whether this condition computes to truth value v in environment env. This makes use of 3-valued propositional logic of Kleene [9], where for example \perp \lor x = x \perp and \perp \land = \perp. The intuition is that \perp stands for either true or false and that equations are valid under this interpretation. This is an abstraction as q \lor \neg q evaluates to \perp in this logic whenever q has value \perp. We note that \perp is strict for comparison operators \( ==, \leq, \) and \( < \) in function certCond. If the condition c is atomic q, we check whether claimed truth value v matches what the environment says about q. If c is \neg c_1, we reduce this to the certification that c_1 has the negated truth value \neg v in the same environment. The cases of conjunction and disjunction are dual and need to consider whether v equals true or false. This structure is also seen in comparing policy sets in a condition, which compares their scores as computed by the environment in function certPSet (\perp indicates no score is present).

The correctness theorem for certification refers to the meaning of Peal+ in environments where all variables have a value from their declared data type Real or Boolean. This operational semantics was given in Section 2 and Figure 2.
Theorem 1 Let $c$ be a Peal+ condition such that the set of policy sets occurring in $c$ is acyclic. Let $v$ be a truth value true or false. Let $I$ be a scenario produced for $c$ from a back-end. Let function $\text{recursivelyCertify}(c, I, v, \emptyset)$ return true and let $env'$ be the value of this environment at program point $l1$. Let $env''$ refine $env'$ such that $env''$ maps no variable to $\bot$. Then condition $c$ evaluates to true in environment $env''$ under the operational semantics of Peal+.

Proof Sketch: We only have to show the claim for function $\text{certCond}$, given the code structure of $\text{recursivelyCertify}$. The claim is proved using structural induction over the condition $c$, noting that sub-conditions also have acyclic sets of policy sets. The cases rely on that fact that $\bot$ is strict for all algebraic operators with noted exception of $\text{eval}(0.0 \ast \bot, env) = 0.0$.

The cases that compare two policy sets require proof of an auxiliary lemma: “Whenever the output of $\text{certPSet}(pS, env')$ is not equal to $\bot$, then that output is the score of policy set $pS$ in all environments that refine environment $env'$.” This is shown for policies and composed policy sets by structural induction.

For the first case of a policy set being a policy, we require a second auxiliary lemma: “Let $pol$ be a policy and $env'$ an environment such that $env'(pol)$ is not equal to $\bot$. Then $env'(pol)$ is the score of policy $pol$ in all environments that refine environment $env'$. ” The proof of this lemma appeals to the linear order in which statically inferred scores of policies are added as hash keys, where $env'$ is of form $env + cp'$ as seen at program point $l2$ in function $\text{recursivelyCertify}$. Since the set of policies occurring in condition $c$ is acyclic, this order is indeed well founded and so we can use well founded induction to prove this lemma. QED

The above theorem (proven in an appendix) says that successful certification of the computed environment $env'$ means that all “completions” of $env'$ that resolve $\bot$ values with any legal value of the respective data type will compute the claimed truth value for the condition in question. In particular, variables $x$ with $env'(x) = \bot$ are genuine “don’t care” variables for this successful certification.

Certification runs in polynomial time in its input: the number of recursions is bounded by $m + n$ where $m$ is the number of declared policies and $n$ the number of predicates occurring in rules. The static analysis of conditions evaluates their parsetree over 3-valued logic, where truth values of leaves are computed by static analyses that are linear in the size of the respective policy sets.

4 Feedback for users

As described in [7], we extract raw Z3 output and render it in pretty printed form, as seen in the initial part of Figure 8. But for larger case studies, it became hard to digest even pretty printed information: one often could not see the forest for all the trees. So we now also output for each analysis a summary of the scenario, its certification, and supporting information. Figure 8 shows typical such output for the Car Rental Risks example. Scenarios also report any non-deterministic choices of uncertainty as seen for variable $b2\_hasOtherLicense\_U$ in that figure. PEALT reports the certification outcome and refinements of predicates and real variables that certification may have brought about (when applicable), lists scores of all policies that certification could statically infer, and then partially evaluates only relevant policies (not for $b3$ in Figure 8) over the successfully certified scenario to then display them in this more compact and meaningful manner. For the latter, true predicates are grouped within square brackets and reported with aggregated score in red (colors not shown in figure), as this is the score for the policy as well. Rules with false
Result of analysis [name2 = always_true? c3]
c3 is (pSet1 <= 50000.0) && (pSet_b4 > 0.4)

c3 is NOT always true, for example, in the scenario in which:
accidentFreeForYears is True, femaleDriver is True, isLuxuryCar is True, mixedUsage is True, speaksEnglish is True, travelsAlone is True, ...
hasEULicense is False, hasOtherLicense is False, hasUKLicense is False, ..., b1_score is 150000, b2_hasOtherLicense_U is 0, b2_risk_score is 1, ...

Certification of analysis [name2] succeeded.
Additional predicates set to false for certification: Set(hasUSLicense, hasEULicense)

Policy scores statically inferred in this certification process:
b1 has score 150000, b2 has score 0.6, b2_risk has score 0.4,
b3 has score 0.25, b4 has score 0.55

Policies in analysis [name2] partially evaluated in certified scenario:
b1 = max (((isLuxuryCar) 150000)) default 50000 ...
b4 = + (((accidentFreeForYears speaksEnglish) 0.55)) default 0

Figure 8: Output format of analyses (handedited to save space): scenario (if applicable), certification status and possible refinements, policy scores inferred during certification, and policies partially evaluated in certified scenario. Variable b2_hasOtherLicense_U functions as $t_2$ in $eval(0.4 [-0.1, 0.1], env)$ and models choice of value from $[-0.1, 0.1]

predicates aren’t shown; in particular, if all predicates are false, an empty policy with default score in red is shown. Rules whose predicates have truth value $\bot$ are shown individually (in green) where predicates end in “?” to mark that they signify don’t care rules.

PEALT uses Z3’s push and pop constructs for incremental solving of more than one analysis. The efficiency may also raise usability issues: the output in Figure 8 was obtained after all other analyses were commented out. If we run all these analyses in their declared sequence, however, the scenario reported for name2 will be different. Similar effects may happen when automated vacuity checking changes its OFF/ON status. On the other hand, this seems at best to make the user temporarily confused and so we don’t think this issue is serious enough to give up the efficiency gains of using the push and pop constructs.

5 Case study: attack-countermeasure trees

Peal+ and its tool PEALT can be used as an intermediate language into which domain-specific languages can be translated and analyzed. Such use has two benefits: analysis results can be certified, and PEALT may perform analyzes that are not supported within the frameworks of those domain-specific languages.

We illustrate these benefits for attack-countermeasure trees (ACTs) [17] by means of an example ACT for a BGP reset of a session as discussed in [17]. The PEALT input code for this example would not really be meant for human consumption, as it would just be an intermediate syntax for facilitating analyses. Our translation extends the semantics of ACTs in that we may turn attack leaves, detection mechanisms, and mitigation mechanisms “on” or “off” – without compromising
Figure 9: ACT from [17] for reset of a BGP session, with detection/mitigation leaves’ probability of working and attack leaves’ success probability, cost, and impact (resp.)

the computation of attack success probabilities, attack impact or attack cost. This, combined with the expressive conditions in PEALT, gives us richer analysis capabilities, discussed in detail below. The full PEALT code for this case study is built into the PEALT tool as an example case study.

Figure 9 shows the ACT taken from [17] where we merely annotated some of its nodes with policy names that we will use in our translation. This tree contains AND and OR nodes as familiar from attack trees [12]. But it also contains three NOT nodes that all feed into parent AND nodes the possible effects of a pair of detection and mitigation mechanisms. Qualitatively, this means that such a pair of working detection and mitigation mechanisms will feed false into the parent AND node. The probabilistic interpretation in [17] is that both mechanisms have a probability of working, and so NOT nodes take as probability the complement of the product of these two probabilities of working mechanisms [17].

The probability of attack success and impact cost are computed over the structure of the ACT [17], whereas attack cost is computed by first producing the set of all min-cuts (as used in fault tree analysis [2]) of the ACT [17]. This makes it hard to reason about the interaction of success probabilities, impact, and cost. Also, it faces scalability issues as the number of min-cuts may be exponential in the size of the ACT. We here want to demonstrate that the use of SMT solvers,
facilitated with Peal+ and PEALT as intermediate language and tool, allows us to reason about such interactions and avoids the need to enumerate all min-cuts.

The declaration of policies for the probability of attack success, the result of policy goal, is shown in Figure 10. A predicate True, asserted to always be true, is used to compose results of children in the ACT. The probability at an OR node with \( n \) children \( x_i \) is \( 1 - \prod_{k=1}^{n}(1 - \text{prob}(x_k)) \), and we expand this arithmetic term in stages using policy scores for stage composition, as seen for policy or1. The probability at an AND node with \( m \) children \( y_j \) is \( \prod_{k=1}^{m} \text{prob}(x_k) \), and we similarly encode this arithmetic expression, as seen for policy and1.

For the encoding of attack leaves, their success probability is the score of a sole rule that captures that attack event. Since attack leaves are not under the scope of a NOT node, their default score is 0. The encoding of a NOT node is simply \( 1 - x \) where \( x \) is the result of its child AND node. For that AND node, the staged computation checks whether both detection and mitigation are present, in which case it computes the product of the probabilities of both mechanisms working; otherwise, it returns 0.0. This default score is sound as it makes the NOT node default to 1.0 which has no effect on its predecessors in the ACT (there is no NOT node in the scope of another NOT node). Thus this translation works for ACTs since they don’t have nested NOT nodes.

In Figure 11, cost of attacks to an attacker and overall attack cost are specified. Default scores capture cost in the absence of attacks and so equal 0.0. In contrast to [17], overall cost is here the sum of all occurring, i.e. true, attacks since analyses ask whether attacks succeed within cost budgets and Z3 will search for such solutions by turning attack leaves “on” or “off” as desired.

The specification of attack impact (given in an appendix) reflects that the impact of an OR node is the maximum of the impact of all its children – modeling a worst-case scenario for the system [17]; and that the impact of an AND node is the sum of the impact of all its children. As in [17], NOT nodes don’t contribute to impact of attack success, although it is noted in [17] that detection and mitigation mechanisms can reduce risk.

Finally, we may specify questions about this ACT in Peal+. Using basic conditions such as \( 549.0 < \text{impact}_{\text{overall}} \) and binary conjunction, we express condition c6 which asks whether the attack impact can be strictly above 549.0, the attack cost can be less than or equal to 440.0, and the probability of attack success can be strictly above 0.41199 – all in the same scenario. PEALT reports that this is possible in a scenario in which attacks a1123, a2, and a12 occur (i.e. are true), as well as detection mechanisms d1 and mitigation mechanism m2. The latter two may be unexpected. But in the scenario neither the mitigation mechanism m1 of d1 nor the detection mechanism d2 of m2 occur (i.e. are false). Therefore, none of the two respective NOT nodes contribute to the probability of attack success; and NOT nodes contribute neither to impact not to cost.

Threshold values chosen in condition c6 are co-dependent: we can’t decrease 440.0 by 1 or more, increase 549.0 by 1 or more, or increase 0.41199 by 0.00001 or more without making condition c6 unsatisfiable. These values were determined by repeated analysis that adjusted these values with bisection search using SAT/UNSAT results to drive the bisection method. It would be of interest to automate such search over objective functions within PEALT in future work. If we add to condition c6 a conjunct, saying that the detection/mitigation pair d2 and m2 also has to occur, PEALT informs us that this is now impossible.

We can also approximate maxima of security metrics, for example a measure of expected system damage \( f(p, i, c) = p \cdot \text{max}(0, 2i - c) \) for attack success probability \( p \), attack cost \( c \), and attack impact \( i \) – exploiting that \( p, i, \) and \( c \) are expressed as policies. For example, 271.9199999999999 < \( f(p, i, c) \) is satisfiable for this ACT whereas 271.92 < \( f(p, i, c) \) is not. All scenarios found in this case study
Figure 10: Policies that compute probability of attack success, even when certain attacks, detection mechanisms or mitigation mechanisms may be absent. Policies for sub-ACTs And2 and And6 are similar to those for And1 and now shown

cost_a111 = +((sendRSTmessageToTCPStack 50.0)) default 0.0
cost_a1121 = +((notify 60.0)) default 0.0
cost_a1122 = +((open 70.0)) default 0.0
cost_a1123 = +((keepAlive 100.0)) default 0.0
cost_a12 = +((TCPsequenceNumberAttack 150.0)) default 0.0
cost_a2 = +((alterConfigurationViaCompromisedRouter 190.0)) default 0.0
cost_overall = +((True cost_a111_score) (True cost_a1121_score) (True cost_a1122_score) (True cost_a1123_score) (True cost_a12_score) (True cost_a12_score)) default 0.0

certified successfully without refining any predicates.

6 Discussion and Evaluation

We analyzed and certified about 20,000 random conditions with uncertainties but a few of these conditions failed to certify. We isolated the source of these failures to be an anomaly of the Z3 push command. With help of Arie Gurfinkel, Nikolaj Bjorner was able to attribute this to Z3 work item 108 (see http://z3.codeplex.com/workitem/108): if some constraints are non-linear, use of push invokes a legacy solver that may report incorrect models for SAT outcomes. Since PEALT won’t use push when a sole analysis executes, we can eliminate this Z3 bug as source of certification failure by turning off vacuity checking and commenting out all other analyses. We think PEALT therefore strikes a good balance between performance (which use of push on more than one analysis greatly improves) and correctness (since failed certifications are rare and caused by this bug or by typos as discussed next).

If a user declares a policy p but also writes p in a score instead of p.score, the SMT solver may find a real value for real variable p (implicitly declared in that rule!) and so env(p) would have that value. If this is not the value one would statically infer for policy p, such aliasing will fail certification. Also, spelling mistakes in variable names may declare new variables that can result in inconclusive certification. Anecdotal evidence suggests that almost all failed or inconclusive certifications are results of such typos, which won’t occur whenever PEALT is used as intermediate language by code generators.

The certification process in PEALT only works for scenarios (whose reported values for policy scores are ignored in certification), not for a claim that no scenario exists. We first focused our efforts on scenarios as they are likely to be more useful to specifiers, and since certification of non-existence of scenarios involves formal proofs extracted from back-ends (e.g. [3]), but general specifiers cannot be expected to understand complex proofs.

The scope of certification does not expand into section DOMAIN_SPECIFICS. For example, assume that a predicate occurs in no rule but is cast to a condition and declared in section DOMAIN_SPECIFICS, which also defines its meaning. Our certification will not inspect this definition of meaning as it is expressed outside of Peal+ in an expressive logic. We did not find this to be limiting when writing and certifying PEALT models, but it means that certification is a relative notion in PEALT. On the other hand, it seems feasible to extend our 3-valued certification to cover DOMAIN_SPECIFICS as well for fragments of Z3’s input language.

Our implementation of Peal+ requires that policies be cast into policy sets (when needed), predicates be cast into conditions (when needed), and operators for policies, policy sets, and conditions be unary or binary (not n-ary). The latter is a good thing, since it means that all sub-conditions of conditions are explicitly declared and so subject to vacuity checking. PEALT does not check whether predicates within a policy occur more than once. The latter is an issue when two or more such occurrences have scores with uncertainty as this “binds” the non-deterministic choice made for these expressions to the same value. Our BGP case study with uncertainties in PEALT addresses this be using True1, True2, etc. to disambiguate this.

PEALT has no explicit ability to model state spaces and their transition; one may see this as a weakness and opportunity for future work, or as a strength as it avoids state space explosions.
7 Related work

We are not aware of much publicly accessible literature on the independent certification of formal methods results and report two results of that type here. For model checking, Namjoshi developed deductive techniques in [15] that can independently verify the results of model checks for formulas of the modal mu-calculus and where these proofs can be extracted from an (instrumented) model checking run. For theorem proving, Gonthier [5] simplified the proof of the famous 4-color theorem, and proved it in the theorem prover Coq in such a manner that the proof itself could be certified as well.

Jha et al. [8] use model checking to automatically generate attack graphs with nodes representing network states, develop techniques for choosing minimal number of security measures and for trading off attack likelihood and attack probability. Attack graphs that express dependencies of vulnerabilities instead, such as those of Albanese et al. [1], have more scalable analyses than state-based ones. Attack graph models in the literature appear to have a fixed model signature, whereas PEALT can extend modeling domains as and when needed.

Language Peal+ extends Peal [4] and the tool PEALT over its version in [7]: PEALT now supports the richer language Peal+, automated vacuity checking of all declared analyses, the automated certification of all scenarios generated by Z3 for analyses, and the partial evaluation of policies over scenarios so that users can comprehend scenario information directly on relevant policies.

In [6], we sketched Peal+ and illustrated it with mock-up syntax for a “score card” model very similar to that from Figure 4. Although that paper discussed usability issues, it focussed on the design of Peal+ and did not cover usability issues of a supporting tool and its user feedback.

8 Conclusions and future work

In this paper we presented a language Peal+ in which the interaction of concepts that inform security and threat analysis can be formally expressed and analyzed. We reported its implementation in tool PEALT that statically analyzes such conditions with two principal aims: to determine whether specified conditions meet expectations of how security-related concepts influence decision making; and to validate that the expectations that users have do not have unintended consequences when expressed and enforced in such conditions.

PEALT reflects the methodology of auto-interactive verification (see Fig. 1). This means users can rely on automated verification tools that provide easily comprehended feedback which may trigger subsequent modeling and automated verification. And this process would be repeated until users are satisfied to have captured conditions as desired. This paper developed foundations for language Peal+ and implemented them in tool PEALT, using the SMT solver Z3 as back-end for automated reasoning and scenario generation to realize this methodology.

We created support for validating scenarios computed for conditions expressed in Peal+: an independent certification of the correctness of scenarios with respect to the domain and policies in which they should be interpreted. We stress that our certification is agnostic to the manner in which code for analysis in back-ends is generated (since certification operates on Peal+ expressions directly) and agnostic to the choice of back-end (apart from an interface for the scenario to be certified and for variables modelling uncertainty). All policies that certification seems to rely upon, PEALT partially evaluates with respect to the certified scenario and provides this as auxiliary feedback, so that modelers may more easily assess the impact of policies certified in possibly refined
scenarios.

We illustrated the utility of Peal+ and these support mechanisms by first discussing a Car Rental Risks example and then attack-countermeasure trees. We showed how ACTs can be translated into Peal+ so that we can reason about interaction of the probability of attack success, attack cost, and attack impact whilst at the same time allow the model to turn attack, detection, and mitigation leaves “on” or “off” at will. Therefore, our ACTs actually represent an entire set of ACTs and we can verify invariants of such interaction over that set of ACTs.

It will be of interest to extend Peal+ with judicious support for integer variables (a potential performance bottleneck for SMT solvers) and optimization with respect to non-linear objective functions. We also mean to develop auxiliary tools that can translate other threat modeling formalisms into PEALT for richer analysis, as illustrated for ACTs in this paper. Finally, we mean to research how we can extend Peal+, PEALT, and our certification to state transitions and to conditions that analyse state changes through operators of temporal logic.

Acknowledgements

We are grateful that this work was supported by funding from Intel® Corporation within its Trust Evidence research project. Charles Morisset and Jason Crampton suggested some of the terminology of Peal and helped with designing some early versions of code generators for Peal. Jason is also thanked for suggesting to improve the presentation of this paper.

B  Formal semantics of policy sets

We here discuss the operational semantics given in Figure 2 in more detail. Let $e$ be an environment for the evaluation of a set of policy sets $\mathcal{P}$. Then $e$ is a function that maps predicates $q_i$ to truth values false or true (written $e(x)$), variables $x$ not of form $p,s$ to a real number ($e(x)$), and declared uncertainty intervals $[l, u]$ to some element of $[l, u]$. It should be noted that intervals are uniquely identified by their policy and predicate (or by their policy if the interval is declared in the default score). So formally, we write $e(pol, q_i, [l, u])$ respectively $e(pol, default, [l, u])$ to also identify the respective location of these intervals.

The operational semantics $\mathcal{E}_e$ for policy sets in $\mathcal{P}$ in environment $e$ is then given in Figure 2. At the top of that figure, we see the computation of the meaning of policy sets using structural induction (policies as base case, and composed policies as other case). For policies, this distinguishes between the case in which no predicate is true in the environment $e$ (the default cause in which $Z$ is empty) and the case when $Z$ is non-empty. The former case also gives meaning to policies that contain no rules. At the bottom of the figure, we see a definition of how score expressions evaluate in environment $e$. This makes use of the contextual information that maps intervals to their declared locations.

It should be clear that this is a well defined semantics whenever the set of policy sets if acyclic.

C  Proof of Theorem 1

It suffices to prove the claim for environment $env'$, provided that the argument made never has to appeal to $\bot$ outputs of $env'$. Given the structure of the code body for recursivelyCerti fy, we only have to show the respective claim for function $certCond$. That is to say, we need to show that condition $c$ has truth value $v$ in environment $env'$ whenever $certCond(c, env', v)$ outputs true. We proceed by structural induction over the condition $c$.

- Let $c$ be a predicate $q$. Then $certCond(q, env', v)$ outputs $v \equiv env'(q)$ which is true. Since $\bot$ is strict for such equality checks, we infer from this that $env'(q) \neq \bot$ and so this is a truth value that must therefore equal $v$, which is either true or false. This shows that condition $q$ has truth value $v$ in environment $env'$, as claimed.

- Let $c$ be $\neg c_1$. Then function $certCond(\neg c_1, env', v)$ returns whatever $certCond(c_1, env', \neg v)$ returns, which is true. By induction on $c$, we infer from this that condition $c_1$ has truth value $\neg v$ in environment $env'$. Therefore, $\neg c_1$ has truth value $\neg \neg v = v$ in environment $env'$, as claimed.

- Let $c$ be $c_1 \land c_2$. There are two cases, one for each value of $v$:
  - Let $v$ be true. Then the value of function $certCond(c_1 \land c_2, env', true)$ equals $certCond(c_1, env', true) \land certCond(c_2, env', true)$ which outputs true. Therefore, we know that both $certCond(c_1, env', true)$ and $certCond(c_2, env', true)$ output true. By induction, we infer from this that $c_1$ has truth value true in environment $env'$, and that $c_2$ has truth value true in environment $env'$. Therefore, $c_1 \land c_2$ has truth value true in environment $env'$, as claimed.
  - Let $v$ be false. Then the value of function $certCond(c_1 \land c_2, env', false)$ equals $certCond(c_1, env', false) \lor certCond(c_2, env', false)$ which outputs true. Therefore,
there is some \( j \) in \( \{1, 2\} \) such that \( \text{certCond}(c_j, env', false) \) outputs \( true \). By induction, we infer from this that \( c_j \) has truth value \( false \) in environment \( env' \). Therefore, \( c_1 \wedge c_2 \) has truth value \( false \) in environment \( env' \), as claimed.

- Let \( c \) be \( c_1 \vee c_2 \). There are two cases, one for each value of \( v \):
  - Let \( v \) be \( true \). Then the value of function \( \text{certCond}(c_1 \vee c_2, env', true) \) equals \( \text{certCond}(c_1, env', true) \vee \text{certCond}(c_2, env', true) \) which outputs \( true \). Therefore, we know that there is some \( j \) in \( \{1, 2\} \) such that \( \text{certCond}(c_j, env', true) \) outputs \( true \). By induction, we infer from this that \( c_j \) has truth value \( true \) in environment \( env' \). Therefore, \( c_1 \vee c_2 \) has also truth value \( true \) in environment \( env' \), as claimed.
  - Let \( v \) be \( false \). Then the value of function \( \text{certCond}(c_1 \vee c_2, env', false) \) equals \( \text{certCond}(c_1, env', false) \wedge \text{certCond}(c_2, env', false) \) which outputs \( true \). Therefore, we know that both \( \text{certCond}(c_1, env', false) \) and \( \text{certCond}(c_2, env', false) \) output \( true \). By induction, we infer from this that \( c_1 \) has truth value \( false \) in environment \( env' \), and that \( c_2 \) has truth value \( false \) in environment \( env' \). Therefore, \( c_1 \vee c_2 \) has truth value \( false \) in environment \( env' \), as claimed.

- Let \( c \) be \( pS_1 \leq pS_2 \). There are two cases, one for each value of \( v \):
  - Let \( v \) be \( true \). Then the value of function \( \text{certCond}(pS_1 \leq pS_2, env', true) \) equals \( \text{certPSet}(pS_1, env') \leq \text{certPSet}(pS_2, env') \) which outputs \( true \). Since \( \bot \) is strict for \( \leq \), we infer from this that both \( \text{certPSet}(pS_1, env') \) and \( \text{certPSet}(pS_2, env') \) are different from \( \bot \). By Lemma 1, this implies that \( \text{certPSet}(pS_j, env') \) is the score of policy set \( pS_j \) in environment \( env' \) for all \( j \) in \( \{1, 2\} \). Therefore, it follows that condition \( pS_1 \leq pS_2 \) has truth value \( true \) in environment \( env' \), as claimed, given that \( \text{certPSet}(pS_1, env') \leq \text{certPSet}(pS_2, env') \) outputs \( true \).
  - Let \( v \) be \( false \). Then the value of function \( \text{certCond}(pS_1 \leq pS_2, env', false) \) equals \( \text{certPSet}(pS_2, env') < \text{certPSet}(pS_1, env') \) which outputs \( true \). Since \( \bot \) is strict for \( < \), we infer from this that both \( \text{certPSet}(pS_1, env') \) and \( \text{certPSet}(pS_2, env') \) are different from \( \bot \). By Lemma 1, this implies that \( \text{certPSet}(pS_j, env') \) is the score of policy set \( pS_j \) in environment \( env' \) for all \( j \) in \( \{1, 2\} \). Therefore, it follows that condition \( pS_1 \leq pS_2 \) has truth value \( false \) in environment \( env' \), as claimed, given that \( \text{certPSet}(pS_2, env') < \text{certPSet}(pS_1, env') \) outputs \( true \).

- Let \( c \) be \( pS_1 < pS_2 \). There are two cases, one for each value of \( v \):
  - Let \( v \) be \( true \). Then the value of function \( \text{certCond}(pS_1 < pS_2, env', true) \) equals \( \text{certPSet}(pS_1, env') < \text{certPSet}(pS_2, env') \) which outputs \( true \). Since \( \bot \) is strict for \( \leq \), we infer from this that both \( \text{certPSet}(pS_1, env') \) and \( \text{certPSet}(pS_2, env') \) are different from \( \bot \). By Lemma 1, this implies that \( \text{certPSet}(pS_j, env') \) is the score of policy set \( pS_j \) in environment \( env' \) for all \( j \) in \( \{1, 2\} \). Therefore, it follows that condition \( pS_1 < pS_2 \) has truth value \( true \) in environment \( env' \), as claimed, given that \( \text{certPSet}(pS_1, env') < \text{certPSet}(pS_2, env') \) outputs \( true \).
  - Let \( v \) be \( false \). Then the value of function \( \text{certCond}(pS_1 < pS_2, env', false) \) equals \( \text{certPSet}(pS_2, env') \leq \text{certPSet}(pS_1, env') \) which outputs \( true \). Since \( \bot \) is strict for
two cases to consider:

Proof:
Again, it suffices to prove this for environment \( \bot \) never appeals to \( \text{env} \) environments that refine environment \( \text{env} \).

Lemma 1
Let \( (\text{certPSet}(\text{recursivelyCerti fify point l2 for function}) \) never appeals to \( \bot \) again, it suffices to prove this for environment \( \text{env} \) outputs of \( \text{env} \).

Proof: Again, it suffices to prove this for environment \( \text{env} \), provided that the argument made never appeals to \( \bot \) outputs of \( \text{env} \). We do structural induction of the policy set \( \text{pS} \). There are two cases to consider:

- Let \( \text{pS} \) be a policy \( \text{pol} \). Then the output of \( \text{certPSet}(\text{pol}, \text{env}) \) is the output of \( \text{certPolicy}(\text{pol}, \text{env}) \) which is \( \text{env}(\text{pol}) \), and so the latter output is not equal to \( \bot \). By Lemma 2, this implies that the score of policy \( \text{pol} \) is the output of \( \text{certPolicy}(\text{pol}, \text{env}) \), as claimed, as this is the output of \( \text{certPSet}(\text{pol}, \text{env}) \).

- Let \( \text{pS} \) be of form \( \text{op}(\text{pS}_1, \text{pS}_2) \) for \( \text{op} \) in \( \{\text{min}, \text{max}, +, *\} \) and policy sets \( \text{pS}_1 \) and \( \text{pS}_2 \). Then the output of \( \text{certPSet}(\text{op}(\text{pS}_1, \text{pS}_2), \text{env}) \) is the output of \( \text{op}(\text{certPSet}(\text{pS}_1, \text{env}), \text{certPSet}(\text{pS}_2, \text{env})) \), which is therefore not equal to \( \bot \). Since \( \bot \) is strict for all operators \( \text{op} \), we infer from this that both \( \text{certPSet}(\text{pS}_1, \text{env}) \) and \( \text{certPSet}(\text{pS}_2, \text{env}) \) are not equal to \( \bot \). By induction, this implies that for all \( j \) in \( \{1, 2\} \) the output of \( \text{certPSet}(\text{pS}_j, \text{env}) \) is the score of policy set \( \text{pS}_j \). Therefore, the operational semantics of \( \text{Peal}^+ \) implies that the score of policy set \( \text{op}(\text{pS}_1, \text{pS}_2) \) is the output of \( \text{op}(\text{certPSet}(\text{pS}_1, \text{env}), \text{certPSet}(\text{pS}_2, \text{env})) \), as claimed. QED

We state and prove the second auxiliary lemma needed in the proof of Lemma 1 above.

Lemma 2
Let \( \text{pol} \) be a policy and \( \text{env} \) an environment such that \( \text{env}(\text{pol}) \) is not equal to \( \bot \). Then \( \text{env}(\text{pol}) \) is the score of policy \( \text{pol} \) in all environments that refine environment \( \text{env} \).

Proof: Again, it suffices to prove this for environment \( \text{env} \), provided that the argument made never appeals to \( \bot \) outputs of \( \text{env} \). Let us write \( \text{env} \) in the form \( \text{env} + \text{cp} \), as seen in program point l2 for function \( \text{recursivelyCerti fify} \). Then \( \text{env}(\text{pol}) \) equals \( \text{cp}(\text{pol}) \) which in turn equals \( \text{certPolicy}(\text{pol}, \text{env}) \) as computed in function \( \text{collectCertifiablePolicyScores}(\text{env}) \). So we know that \( \text{certPolicy}(\text{pol}, \text{env}) \) is different from \( \bot \), meaning that we have only two cases to consider in its body. In these cases, we apply well founded induction on the (linear) order in which hash keys \( \text{env}(\text{p}) \neq \bot \) were added to \( \text{env} \) for declared policies \( \text{p} \). Since there are no circular dependencies in the use of score variables for policies, this order is indeed well founded.

- **First case:** Let \( X_{\text{env}}^{\text{pol}} \) be empty. Then \( \text{env}(\text{pol}) \) equals \( \text{eval}(\text{s}, \text{env}) \) where \( \text{s} \) is the default score of policy \( \text{pol} \). In particular, \( \text{eval}(\text{s}, \text{env}) \) is different from \( \bot \). We do a case analysis over the structure of score \( \text{s} \):
– Let $s$ be a constant real $a$. Then $eval(a, env)$ is defined to be $a$ and this is the score of $pol$ as all rules in that policy have false predicates in environment $env$, and so also in its refinement $env'$.

– Let $s$ be a policy score variable $p\_score$ for some declared policy $p$. Then $eval(p\_score, env)$ is not $\bot$ and so it is defined as $env(p)$. In particular, $env(p)$ is not equal to $\bot$. So this key must have been added to $env$ prior to the key for $pol$. We can therefore appeal to well founded induction on the order in which such keys are added to conclude that $env(p)$ is the score of policy $p$ in environment $env$, and so in its refinement $env'$ as well. But then this is also the score of $pol$ in these environments.

– Let $s$ be a real variable $x$ not of form $p\_score$. Then $eval(x, env)$ is not equal to $\bot$ and so it equals $env(x)$. The latter then is the score of $pol$ as all rules in that policy have false predicates in environment $env$, and so also in its refinement $env'$.

– Let $s$ be of form $a * p\_score$ for a constant $a$ and some declared policy $p$. Then $eval(a * p\_score, env)$ is not equal to $\bot$. This implies that $env(p)$ is not equal to $\bot$ or that $a$ equals 0.0. In the latter case, it is clear that 0.0 is the score of policy $pol$ in $env$ and so in all of its refinements. It remains to consider the case when $a$ is non-zero and $env(p)$ is not $\bot$. Then $eval(a * p\_score, env)$ equals $a * env(p)$. Since $env(p)$ is not equal to $\bot$, this key $env(p)$ must have been added to $env$ prior to the key for $pol$. We can therefore appeal to well founded induction on the order in which such keys are added to conclude that $env(p)$ is the score of policy $p$ in environment $env$. Thus, $a * env(p)$ is the score of policy $pol$ in these environments.

– Let $s$ be of form $a * x$. Then $eval(a * x, env)$ is not equal to $\bot$. In particular, $env(x)$ is not equal to $\bot$ or $a$ equals 0.0. In the latter case, it is clear that 0.0 is the score of policy $pol$ in $env$ and so in all of its refinements. It remains to consider the case when $a$ is non-zero and $env(x)$ is not $\bot$. Then $a * env(x)$ is the default score of policy $pol$ in environment $env$ and all its refinements, as claimed.

– Let $s$ be of form $t_1 [l, u]$ where $t_1$ is one of the raw score expressions of the previous items and variable $t_2$ models the non-deterministic value from interval $[l, u]$. Since $eval(s, env)$ is not equal to $\bot$, we know that $env(t_2)$ is not equal to $\bot$ and that $eval(s, env)$ equals $eval(t_1, env) + env(t_2)$. In particular, $eval(t_1, env)$ is not equal to $\bot$ as $\bot$ is strict for $\bot$. And we already reasoned that in this case $eval(t_1, env)$ is the default score of the version of $pol$ that won’t contain interval $[l, u]$ in its default score. Thus, adding $env(t_2)$ to this yields the default score of policy $pol$ as claimed.

* Second case: Let $X_{env}^{pol}$ be non-empty. Then $certPolicy(pol, env)$ outputs $op(X_{env}^{pol})$. As the latter is not equal to $\bot$ and $\bot$ is strict for $op$, we infer from this that $eval(s_i, env)$ is not equal to $\bot$ for all $s_i$ with $env(q_i) = true$. As in the first case when $X_{env}^{pol}$ is empty, we can analyze the structure of each score $s_i$ to show that $eval(s_i, env)$ is the score of rule $(q_i, s_i)$ in policy $pol$ in environment $env'$. Thus, $op(X_{env}^{pol})$ equals the score of policy $pol$ in environment $env$, and so it its refinement $env'$. QED

### D Example of certification failure due to push Z3 bug

Figure 12 shows $PEALT$ input that, when run with option “General scores”, will successfully certify the first analysis but where certification fails for the second analysis. If we then turn
automated vacuity checking OFF under “Settings”, comment out the first analysis, and run this again, \textit{PEALT} will now successfully verify the second analysis. The reason is that only one analysis in total then executes, which \textit{PEALT} will realize and so it will avoid the use of the \texttt{push} construct in this case.

E Termination of certification

The criterion that policies within conditions are acyclic is sufficient but not necessary. For example, the condition in Figure 13 is cyclic but our tool will find and successfully certify a scenario for its analysis – \textit{PEALT} does not do any dependency analysis. But adding as domain-specific constraint that q1 and q3 are true makes the certification not terminate, and so no output will be reported unless users instead generate Z3 code and raw Z3 output without certification.

F Computation of attack impact for our case study

Figure 14 shows how our \textit{PEALT} input models the computation of the impact of an attack.
