## Problem Sheet 3 —

- What is a pooling layer in a Convolutional Neural Network? What is the difference between Max pooling and Average pooling?
  - What are the stride and padding parameters in a convolutional layer?
  - A CNN architecture is described in the table below and takes as input an image and produces a 10-dimensional probability vector and is trained using cross-entropy loss. The architecture consists of max pooling layers as well as convolutional layers.

layer	0	1	2	3	4	5	6	7
type	input	conv	pool	conv	pool	conv	conv	loss
num. filters	-	5x5x1	2x2	5x5x20	2x2	4x4x50	1x1x500	-
stride	-	1	2	1	2	1	-	-
padding	-	0	0	0	0	0	0	-
data shape	1x28x28x1							
receptive field	1							

The input is a  $1 \times 28 \times 28 \times 1$  tensor representing  $batch \times width \times height \times channels$ . Calculate the data shape and receptive field for each layer.

- Standard precision numbers take up 4 bytes per number. Half precision takes only 2 bytes per number. What are the advantages and disadvantages of using half precision?
- Many CNN training problems are compounded by a lack of available training data. Describe some data augmentation techniques to artificially increase the amount of training data. Some of these techniques are performed at training time on the mini-batch before the forward pass. Suggest why?

2. (a) In a classification problem with three classes, a model will output a  $1 \times 3$  vector,  $c$ , that predicts how strongly the input belongs to a class. However, we want a probability vector,  $p \in \mathbb{R}^{3 \times 1}$ . Such a probability vector must sum to 1 and each element must be positive. To ensure this a Softmax function is used which looks like:

$$\mathbf{Given } c = \begin{bmatrix} c_1 \\ c_2 \\ c_3 \end{bmatrix} \tag{1}$$

$$p_i = \frac{e^{c_i}}{\sum_{k=1}^3 e^{c_k}} \forall i, k \in 1, 2, 3 \tag{2}$$

Verify whether  $p$  fulfils the necessary criteria of all elements being non-negative and summing up to 1.

- (b) Compute the derivative  $\frac{\partial p_i}{\partial c_j}$ . Consider the two scenarios when  $i = j$  and  $i \neq j$ .
- (c) Suppose that an image,  $I$  is corrupted by white (Gaussian) noise  $n \sim N(0, \sigma^2)$  giving us the result  $Y = I + n$ . One approach to denoising the image is to take  $N$  snapshots of an object from the same view, yielding multiple images and then taking the average of all the images. Here, each image is given by  $Y_i = I + n_i \forall i \in 1, \dots, N$ . Taking the average of the  $N$  noisy images yields the denoised image  $Y_d = \frac{1}{N} \sum_N Y_N$ . Derive the mean,  $\mu_d$ , and variance,  $\sigma_d^2$ , of the denoised image  $Y_d$ .
- (d) Given an image:

3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65
3	4	8	10	22	45	50	65

And the horizontal and vertical  $3 \times 3$  Prewitt filter kernels:

$$h_x = \begin{pmatrix} 1 & 0 & -1 \\ 1 & 0 & -1 \\ 1 & 0 & -1 \end{pmatrix}$$

$$h_y = \begin{pmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & -1 \end{pmatrix}$$

Assuming zero padding, compute the gradient magnitude of the second row after convolving with both kernels.

- (e) Repeat the previous question but now use reflection (mirrored) padding.
3. (a) What is the difference between invariance and equivariance? Is convolution either of these?
- (b) What is a 2D separable filter? Are all 2D filters separable?
- (c) Is the following 2D filter separable?

$$F = \begin{pmatrix} 2 & 3 \\ 1 & 1 \end{pmatrix}$$

If so separate it, otherwise explain why it is not separable.

- (d) A CNN has four consecutive  $3 \times 3$  convolutional layers with stride 1 and no pooling. How large is the support of a neuron in the fourth layer?
- (e) Why are skip connections used in deep CNN architectures such as ResNet?
- (f) Calculate the (big O) computational complexity of applying both separable and non-separable  $K \times K$  Gaussian filters to an  $N \times N$  image.
